Histologically, the mycosis is characterized by the formation of compact granulomas containing few fungal elements in most patients; however, A/SAF or CF patients with severe disseminated disease have predominantly loose granuloma formation (Restrepo *et al.*, 1976; Brito and Franco, 1994). Lung involvement is secondary to a chronic lymphangitic process provoked by the fungus itself and the host's response represented by formation of granulomas and fibrosis, the latter of which predominates at the perihilar region (Tuder *et al.*, 1985). This aspect correlates with the butterfly-like (perihilar) micronodular and interstitial infiltration observed on plain films (Funari *et al.*, 1999; Souza *et al.*, 2006). Obstruction and reversal of lymphatic flow would lead to the spread of the inflammatory process throughout the lungs (Tuder *et al.*, 1985). The granulomatous inflammation is associated with a mixed pyogenic component, especially in the case of ulcerated skin lesions or ruptured lymph nodes (Franco *et al.*, 1989). Caseation and central necrosis may be present. In compact granulomas, abundant epithelial cells, Langerhans or foreign-body giant cells, plasmocytes, and lymphocytes are seen; often, phagocytosis of the yeast cells can be observed. CD4⁺ lymphocytes dominate over CD8⁺ lymphocytes and appear as peripheral mantles around aggregates of macrophages and histiocytes (Moscardi-Bacchi *et al.*, 1989). In the A/SAF and CF patients with disseminated disease, the inflammatory reaction is loose, with abundance of both mononuclear and yeast cells but sparse formation of compact granulomas (Tuder *et al.*, 1985; Franco *et al.*, 1989; Brito and Franco, 1994). Loose granulomas appear unable to circumscribe fungal antigens, and at their periphery, *Paracoccidioides* spp. antigens may permeate throughout the intercellular space (Sandoval *et al.*, 1996). Skin and mucous membrane lesions usually exhibit pseudoepitheliomatous hyperplasia and intraepithelial microabscesses (Franco *et al.*, 1989; Moscardi-Bacchi *et al.*, 1989). The role of neutrophils in the inflammatory response against *paracoccidioides* spp. has recently been reinvestigated and it was shown that neutrophil extracellular traps are present in tegumentary lesions of patients (Della Coletta *et al.*, 2015).

An important aspect drawn from the previously described histologic studies is the frequent description of areas of active disease characterized by pyogenic reaction and loose granulomata, rich in budding fungal cells, intermingled with areas with compact granulomas, rare fungal cells, and variable degrees of fibrosis (Tuder *et al.*, 1985). This mixed aspect can be observed in pulmonary, oro-pharyngeal and skin lesions, and even in lymph nodes, suggesting that the disease evolves through localized new bouts of fungal multiplication and tissue invasion, whereas the adjacent older lesions are in their way to fibrotic resolution. CT scans of the lung confirmed this aspect by depicting areas with alveolar condensation along with fibrotic and emphysematous zones and the simultaneous presence of features of more recent and chronic lesions (Funari *et al.*, 1999; Souza *et al.*, 2006).

Tissue reactions are nonspecific; thus, diagnosis depends on finding *P. brasiliensis*. If the parasite is abundant, it may be identified by hematoxylin and eosin stains. Special fungal stains (e.g., Grocott silver methenamine), however, always should be employed, especially when granulomata are examined. The typical multiple budding yeast cells must be found to establish a diagnosis. The presence of fungal cells of different sizes (2–40 µm) suggests the presence of *P. brasiliensis*. In some cases, short chains and cells with single buds also are observed, and in these patients, differentiation of *P. brasiliensis* from *Cryptococcus neoformans*, *Blastomyces dermatitidis*, and even *Histoplasma capsulatum* and *Pneumocystis jirovecii* must be made (Brummer *et al.*, 1993; Silletti *et al.*, 1996). When the disease is chronic, most of the fungal cells are found inside the macrophages, but free yeast cells predominate in disseminated cases. Internalized yeast cells exhibit altered morphology (Restrepo, 2000).

As other chronic granulomatous diseases, PCM is a spectral disease, with the A/SAF characterized by poor cellular immune responses, high fungal burden, high anti-*Paracoccidioides* antibody titers, including those of the IgG4 and IgE subclasses, eosinophilia, all of which typical of a predominance of Th-2 over Th-1 immune responses (Benard, 2008). Conversely, some patients with the chronic form have a more localized disease, low fungal burden, compact granulomas and low antibody titers, suggesting that they are still able to mount Th-1 responses. In between would stay the chronic multifocal patients with deficient Th-1 type responses without marked shift to Th-2 responses (Benard, 2008). However, the simplistic view of a Th-1/Th-2 paradigm of immune response has been challenged by the description of other subset of T cells such as T regulatory cells, Th-17 cells, Th-9 cells and Th-22 cells. The clinical phenotypes presented by PCM patients have been associated with these subsets. A/SAF patients displayed predominantly a mixed Th2/Th9 response while in CF patients there was a balance between Th-1, Th-17 and Th-22 responses depending on the extent of the disease in these patients (de Castro *et al.*, 2013). Recent data demonstrated that the NLRP3 inflammasome was essential for the activation and expansion of Th17 and Th1 cells upon challenge in vitro with *P. brasiliensis* yeast cells, while inhibition of this receptor by DC lead to increased Th2 and Treg frequency (de Castro *et al.*, 2018). Fig. 5 describes a proposed scheme of the cellular immune response profiles of patients with PCM, based mostly on data from

studies of patients' immune responses, the focus of this review. Apparently, the severity of the disease is driven mainly, on one side, by the host's genetic background and immune response status and, on the other side, by the size of the inoculum, rather than peculiarities of fungus isolate. The immunogenicity and pathogenicity of *P. brasiliensis* samples freshly isolated from patients with PCM were tested in mice to compare with the severity of disease of the isolate's donor but a well defined relationship between pathogenicity of the fungal isolate in mice and the clinical findings of the correspondent patient was not evident (Sadahiro *et al.*, 2007). On the other hand, the mechanisms responsible in vivo for killing of the fungus are not yet known. *In vitro* studies showed that hydrogen peroxide (H₂O₂) released by normal human macrophages activated by Th-1 cytokines, kills yeast cells of *Paracoccidioides* sp. (Carmo *et al.*, 2006). Resting human macrophages are otherwise unable to kill the fungus or to handle the fungal cell wall of phagocytosed yeast cells (Lenzi HL., unpublished data). Others have shown that NK cells are able to recognize and kill in vitro *P. brasiliensis* as well as *P. brasiliensis*-infected monocytes (Longhi *et al.*, 2012). They also found that NK cells from PCM patients exhibit a lower cytotoxic response compared with healthy individuals.

Clinical Manifestations

As yet, there is no differentiation between the clinical manifestations caused by the two *Paracoccidioides* species, *brasiliensis* and *lutzi*, in a same fashion to what is observed with the disease caused by *C. immitis* and *C. posadasii*. PCM is a polymorphic disorder that may affect any system and organ. The current classification of the mycosis relies not only in the organs/systems involved but also in the host's immune status and the natural history of the disease (Franco *et al.*, 1987). The classification comprises a subclinical form (PCM-infection), the PCM-disease, which is subdivided into A/SAF, CF and mixed form, and a residual form. The A/SAF form predominates in children and young adults, though the denomination of juvenile form, while the CF affects adults and aged people, and is thus also named adult form. According to the severity of the disease, the A/SAF may be severe and moderate. The CF may apparently be restricted to the lungs or disseminated. As stated earlier, the degree of dissemination will depend on the availability of diagnostic procedures. Disseminated disease is characterized by involvement of the oral and upper respiratory mucosa, reticuloendothelial system, adrenal glands, skin and central nervous system; and, less frequently, gastrointestinal or genitourinary tract and bones (Giraldo *et al.*, 1976; Restrepo *et al.*, 1976; Mendes, 1994; Bellissimo-Rodrigues *et al.*, 2013). In more than 80% of the disseminated cases there is concomitant lung involvement, probably the initial localization from which distant foci were established through lymphohematogenous route. The CF can be mild, moderate, or severe (Franco *et al.*, 1987). It has been proposed that the disease presented by immunocompromised patients such as those with HIV-infection would correspond to a new, mixed form (Benard and Duarte, 2000). This mixed form was further substantiated by case-control studies (Morejón *et al.*, 2009; Almeida *et al.*, 2017). Finally, a fraction of the patients remains with fibrotic, residual lesions which may compromise their full health recovery, and thus are classified as having the residual form (Franco *et al.*, 1987; Shikanai-Yasuda *et al.*, 2017).

Fig. 5 Proposed schematic view of the immune network that takes place in the main outcomes of the paracoccidioidomycosis host-parasite interaction. Note that the three main outcomes, healthy infected, A/SAF and CF, are also an oversimplification of the polymorphic clinical spectrum of the disease. Infection initiates when inhaled *Paracoccidioides* conidia reach terminal bronchi or alveolar spaces, where they interact with and are phagocytosed by alveolar macrophages. These cells, harboring live and/or dead fungal elements, migrate to draining lymph nodes where transformation into dendritic cells and antigen presentation take place. DC-T cell interaction will then trigger three types, eventually overlapping, immune networks. In HI (lower part), DCs express NLRP3 and secrete predominantly IL-12 which drives activated T cells to differentiate into Th-1 cells, expressing the transcriptional factor Tbet and Th-1 cytokine signaling molecules STAT-1 and STAT-4, while expressing the β 1 and β 2 subunits of the IL-12R. These in turn release IFN- γ and TNF- α and activate macrophages to phagocytose and kill the yeast cells. Macrophages in this case express the pro-inflammatory cytokine signaling molecule STAT-1. Overall, this network leads to formation of compact granulomas and control/resolution of the infection. In the A/SAF (upper part), DCs do not express NLRP3 and release predominantly IL-10 and IL-4, which activate Th-2 cells; other T cell subtypes (Treg, Th-9) are also expanded and activated. Gata3 and STAT-6 expressing Th-2 cells induce eosinophilia (via IL-5 release), B-cells production of anti-*Paracoccidioides* IgE and Ig4 (via IL-4 release), but disarm macrophages via IL-10 release, which upregulate the inhibitory cytokine signaling molecule STAT-3, and as such *Paracoccidioides* yeast cells are not contained and loose granuloma formation ensues. The expanded *Paracoccidioides*-activated Tregs seen in these patients also contribute to the poor cellular immune response and poor granuloma formation. Expanded activated Th-9 cells drive massive anti-*Paracoccidioides* IgG1 and IgG2 isotype production. In the CF (middle part), which comprises patients with mild, localized disease to "localized" but severe lungs involvement to disseminated disease, present immune networks that may or may not be closer to either that of the HF or that of the A/SAF. In CF patients, the dormant yeast cells within clinically silent foci established during the initial infection, for yet unknown reasons, reactivate. DCs at these sites, upon challenge with the fungi, express NLRP3 but secrete predominantly the pro-inflammatory cytokines IL-6, IL-1 β and TGF- β , which activates T-cells toward a Th-17 phenotype, the hallmark of the CF, but also Th-22. In parallel, the lack of Th-1 activation, resulting in less well activated (STAT-3+) macrophages favor further destabilization of the granuloma. Th activated Th cells also lack expression of the β 2 subunit of the IL-12R but express the intracellular transcriptional factor ROR γ T. Both Th subtypes are responsible for the secretion of several cytokines, among them IL-6, IL-22, IL-17, that induce mucosal inflammation with prominent participation of neutrophils. Tregs and Th-9 are also important participants in the CF immune network. The net result is a variable mix of well-formed granuloma that can limit the infection and loose granuloma that correspond to foci of active disease. Note that the arrows arising from the CF to both the A/SAF and HI outcomes indicate that both Th2 and Th-1 responses may be part of the CF network, depending on the extent and severity of the patient's disease. The factors that dictate the patient's progression to one or another outcome are as yet unknown. Adapted from Benard, G., 2008. An overview of the immunopathology of human paracoccidioidomycosis. *Mycopathologia* 165, 209–221. doi:10.1007/s11046-007-9065-0. de Castro, L.F., *et al.*, 2013. Characterization of the immune response in human paracoccidioidomycosis. *Journal of Infection* 67, 470–485. doi:10.1016/j.jinf.2013.07.019, with modifications.

Patients with A/SAF develop signs and symptoms of a wasting process. Fever, malaise, listlessness, weight loss, and emaciation are recorded frequently (Benard *et al.*, 1994; Londero *et al.*, 1996; Nogueira *et al.*, 2006; Benard and Mendes-Giannini, 2019; Romaneli *et al.*, 2019). The A/SAF is a disease of the reticuloendothelial system resulting in damage of the corresponding organs. Superficial lymph node enlargement is the predominant sign in over 80% of these cases (Londero *et al.*, 1996; Benard and Mendes-Giannini, 2019; Romaneli *et al.*, 2019). Cervical and submandibular lymph node chains are involved most commonly, followed by those of the supraclavicular and axillary regions; however, any chain can be affected. Lymph nodes may vary in size from slightly enlarged to large, painful, coalescent masses; some may progress to fistulization draining purulent material rich in yeast cells.

Hepatomegaly and splenomegaly, usually asymptomatic, are the second most common finding in the A/SAF. In a report of 63 cases of PCM in children under age 16 liver involvement was detected in 40%, of whom 68% presented hepatomegaly and 29% jaundice (Pereira *et al.*, 2004). A more recent survey of 142 cases under 15 years-old found slightly lower frequencies of hepatomegaly (~30%) and splenomegaly (20%) (Romaneli *et al.*, 2019). Liver enzymes, especially alkaline phosphatase and gamma-glutamyl transferase are frequently but not markedly increased (Nogueira *et al.*, 2006). Gross hepatic lesions may not be apparent, but histopathologic examination regularly reveals fungal invasion of this organ in the more severe cases (Benard *et al.*, 1994; Boccalandro and Albuquerque, 1960; Londero *et al.*, 1996), as also revealed by a study of a series of fatal cases (Teixeira *et al.*, 1978). The presence of yeast cells in the liver was associated with a granulomatous tissue response. Splenic lesions are nodular or military. Portal hypertension is a rare occurrence. Importantly, a study showed that liver involvement was associated with younger age, more severe anemia, hypoalbuminemia and malnutrition and eventually higher risk of death (de Melo Braga *et al.*, 2013). Findings and complaints relating to the abdomen and digestive tract, such as presence of abdominal masses, lymph node enlargement, diarrhea, vomiting, abdominal distention or pain, and ascites, also have also been recorded in a sizable proportion of A/SA form patients (Benard *et al.*, 1994; Londero *et al.*, 1996; Pereira *et al.*, 2004; de Melo Braga *et al.*, 2013; Romaneli *et al.*, 2019). Hypertrophied lymph nodes, usually generalized but particularly periaortic, around the hepatic hilum and retroperitoneally, can be detected by US, CT scans or MRI (Martinez *et al.*, 1988). Signs and symptoms of an acute abdomen, caused by masses formed by hypertrophied lymph nodes that may become palpable or perforation, also have been reported. These coalescent masses may result in pathology caused by extrinsic compression of adjacent structures, such as jaundice by compression of the biliary duct, pancreatitis, intestinal occlusion, and blockade of lymphatic drainage followed by ascites (Benard *et al.*, 1994; Londero *et al.*, 1996; Pereira *et al.*, 2004; de Melo Braga *et al.*, 2013; Benard and Mendes-Giannini, 2019; Romaneli *et al.*, 2019). In fact, histopathologic examination of autopsies (likely the more severe cases) showed a specific granulomatous enteritis in 80% (Fonseca and Mignone, 1976). Additionally, in a MRI study of patients mostly with the A/SAF, 48% had abdominal lymph node enlargement, even if no abdominal signs and symptoms had been recorded (Martinez *et al.*, 1979b). This lymph node involvement can cause mesenteric lymphatic stasis and enteric mucosal edema that may progress to fungal enteritis accompanied by abnormal intestinal function such as reduced absorption of fat (Martinez *et al.*, 1979b; Shikanai-Yasuda *et al.*, 1992a,b; Benard *et al.*, 1996; Nogueira *et al.*, 2006; de Melo Braga *et al.*, 2013). Patients may thus develop a disabsorptive syndrome that aggravates the nutritional and immune status. Abdominal complications are still being sporadically reported despite improved diagnosis and treatments (Romaneli *et al.*, 2019). Digestive involvement may eventually be observed in CF patients with severe disseminated disease. The pathogenesis and manifestations are similar to those of the A/SAF, with primary involvement of the lymphatics causing lymph node enlargements, hepatosplenomegaly and ulcerative enteritis (Martinez *et al.*, 1979a,b).

Studies also have shown bone marrow infiltration mainly, but not exclusively, in the A/SAF of the disease (Resende *et al.*, 2006). Bone lesions and articular involvement may be important components of the severe forms of the disease, especially in younger children. In these patients, the long bones were frequently affected, with the lytic lesions located at the diaphyseal or metaphyseal-epiphyseal regions (Doria and Taylor, 1997; Pereira *et al.*, 2010; Correa-de-Castro *et al.*, 2012; Monsignore *et al.*, 2012), probably because of their higher vascularization, emphasizing the hematogenous dissemination that typically occurs in this form of the disease. Ribs, skull, phalanges, and vertebral lytic lesions also have been documented. Differently from the painful, motion-restriction joint lesions, the bone lesions can be silent or oligosymptomatic (Doria and Taylor, 1997; Monsignore *et al.*, 2012). A pathologic fracture may occasionally occur (Cimerman *et al.*, 1997).

Skin lesions were noted in 20%–30% of the A/SAF cases, with a tendency toward higher frequency with increasing patient age (Fig. 6). Distribution of cutaneous lesions was variable, but face and trunk were involved more frequently. Acute-subacute paracoccidioidomycosis: A pediatric cohort of 141 patients, exploring clinical characteristics, laboratorial analysis and developing a non-survival predictor (Londero *et al.*, 1996; Nogueira *et al.*, 2006; Romaneli *et al.*, 2019). Lung abnormalities were recorded in a small proportion of cases. However, even in the absence of clinical and radiologic involvement, colonization of the lung by *Paracoccidioides* spp. can be demonstrated by direct examination and by culture (Restrepo *et al.*, 1989). When chest radiographs (Fig. 7) were abnormal, enlarged hilar lymph nodes was the most common abnormality; military or interstitial infiltrates were occasionally seen (Campos *et al.*, 1992; Londero *et al.*, 1996; Benard *et al.*, 2005; Martinez and Moya, 2009). In contrast with the CF, where adrenal involvement is a serious concern, it is uncommon in the A/SAF. A survey of adrenal function before and after treatment in 23 children with the A/SA disease showed normal adrenal function (Pereira *et al.*, 2006).

Anemia, an increased erythrocyte sedimentation rate, severe hypoalbuminemia, and hypergammaglobulinemia with high IgG serum concentrations are found regularly (Londero *et al.*, 1996; Nogueira *et al.*, 2006; Romaneli *et al.*, 2019). Nonetheless, anti-*Paracoccidioides* antibodies may prove undetectable in some patients with localized disease and low fungal burden or due to the production of low avidity antibodies (Neves *et al.*, 2003). Eosinophilia, as well as elevated IgE antibody titers, has been detected in most patients (Yarzabal *et al.*, 1980; Shikanai-Yasuda *et al.*, 1992a,b; Biselli *et al.*, 2001; Mamoni *et al.*, 2002; Nogueira *et al.*, 2006). Recently, it was proposed that the serum albumin level could predict the outcome of children with PCM: an albumin cutoff ≤ 2.18 g/dL on admission had a

Fig. 6 Patients with the chronic form of the disease presenting characteristic muco-cutaneous lesions: hard palate ulcerated lesions with the typical moriform stomatitis aspect, ulcerated and infiltrative cutaneous facial lesions, and ulcerated lesions of the lips.

85.7% sensitivity and 85.4% specificity for non-survival outcome while values above 2.18 g/dL translated into a 99.1% chance of survival (Romaneli *et al.*, 2019). Studies of other cohorts should be performed to validate this prognostic factor.

The lungs are the target organ in the CF. The respiratory symptoms are nonspecific and, in most cases, evolve slowly, albeit progressively, thus delaying the diagnosis. Many patients attribute their symptoms to the smoking habit, related by ~90% of the patients with the CF (Costa *et al.*, 2013; Peçanha *et al.*, 2017). Smoking appears to be a risk factor for the development of the CF PCM (dos Santos *et al.*, 2003). Main symptoms are short breathiness, mild dyspnea, dry cough, occasionally with sputum production and, in lesser proportions, hemoptysis. These symptoms may be accompanied by systemic symptoms such as fatigue, weight loss and asthenia. Lung auscultation reveals abnormalities in less than half of the patients; furthermore, at diagnosis over 20% of patients with several alterations on lungs radiological exams exhibit very mild symptoms and no alterations on pulmonary auscultation, a clinic radiological dissociation early observed in this mycosis (Franco *et al.*, 1989; Mendes, 1994; Gomes *et al.*, 2008). Fibrosis is frequently observed already at diagnosis (Campos *et al.*, 2008; Valle *et al.*, 1992; Mendes, 1994; Tobón *et al.*, 2003; Costa *et al.*, 2013). In fact, patients seek medical assistance for oropharyngeal lesions with the pulmonary involvement being diagnosed subsequently through imaging exams. CT scans main findings, according to the Fleischner Society's Glossary of Terms (Austin *et al.*, 1996), are ground-glass attenuation, small centrilobular nodules, cavitated nodules, large nodules, parenchymal bands, areas of cicatricial emphysema, interlobular septal thickening, and architectural distortion (Funari *et al.*, 1999; Souza *et al.*, 2006; Costa *et al.*, 2013). Cavitations and air-space consolidation are also found (Funari *et al.*, 1999; Souza *et al.*, 2006; Costa *et al.*, 2013). These abnormalities are bilateral and tend to be symmetrical. Hilar lymph node enlargements can be found. The reversed halo sign, defined as central ground-glass opacity surrounded by a crescent or ring of consolidation, is observed in up to 10% of patients with PCM (Gasparetto *et al.*, 2005). Pulmonary function tests show an obstructive pattern affecting mainly the small airways: probably both the fungus and smoking contribute the ventilation/perfusion alterations and alveolo-interstitial destruction (Lemle *et al.*, 1983; Campos *et al.*, 2008; Costa *et al.*, 2013). Smoking alone could probably explain these alterations in some patients (Gomes *et al.*, 2008). However, in 30% of the patients receiving an adequate course of therapy, pulmonary fibrosis will appear *de novo* or will consolidate if preexisting, such that by the end of the treatment period this sequela will be documented in over 50% of the cases by chest X-ray, or even higher percentages when CT scans are employed (Tobón *et al.*, 2003; Costa *et al.*, 2013).

Lesions in the oropharyngeal and laryngeal mucosa occur frequently in the CF (Mendes, 1994; Sant'Anna *et al.*, 1999; Fig. 5). Hoarseness, localized pain, dysphagia, and dyspnea (due to tracheal stenosis) are main complaints. Deaths due to suffocation have been recorded, and immediate laryngoscopic evaluation is highly recommended in patients reporting laryngeal stridor and dyspnea. Urgent tracheostomy may be indicated in these cases (Campos *et al.*, 1986). Lesions in the oral cavity are particularly painful, and can affect the teeth and gum, which results in difficulties in chewing the aliments and significant weight loss. There is not a uniform or typical aspect of the lesions: they may be infiltrative, ulcerated, nodular, or vegetative, and may mimic squamous cell carcinoma. However, they usually have a granulomatous superficial aspect (Mendes, 1994; Migliari *et al.*, 1998; Sant'Anna *et al.*, 1999): the base of the ulcerated lesions usually is covered by small abscesses (the mulberry-like lesions) that probably represent fungal dissemination through the lymphatic system because they usually are accompanied by regional lymph node involvement (Uribe *et al.*, 1987; Castro *et al.*, 1999). In the A/SAF, mucosal lesions are rather exceptional, but skin

Fig. 7 Typical pulmonary involvement in the chronic form of the disease. Patient one, chest X-ray (left) showing typical bilateral infiltrates on admission, and thoracic CT scans showing the parenchymatous lesions before (upper) and their improvement during antifungal therapy (lower). Patient two, on the left, chest X-ray showing typical bilateral infiltrates and thoracic CT scan showing the parenchymatous lesions on admission; on the right, chest X-ray and CT scan taken at the end of the antifungal therapy: note the presence of residual abnormalities such as small opacities and nodules, fibrosis, bronchial thickening and small area still with ground glass aspect.

involvement occurs more commonly and tends to be multiple, in contrast with the CF ([Mendes, 1994](#); [Marques *et al.*, 2007](#)). In the latter, lesions are represented mostly by contiguous involvement of the periorificial mucosal lesions or draining lymph nodes. In both the A/SA and chronic severe disseminated form, they represent hematogenous spread of the fungus. In this case, the lesions may appear as ulcerated or ulcero-vegetative lesions, papules, or crust-covered ulcers and warts, usually at the same stage of

Fig. 8 Brain CT scan showing a pseudotumoral lesion in a patient with the chronic form of the disease.

development (Mendes, 1994; Marques *et al.*, 2007). Skin involvement may rarely present as sarcoidic like lesions (Coelho *et al.*, 2016). Mucosal and skin lesions usually are the first ones to resolve with treatment.

The adrenals often are involved in patients with the chronic form of the mycoses, with a small proportion of the patients evolving to overt adrenal hypofunction or insufficiency (Addison disease). A study showed that adrenal reserve was reduced in 44% of the patients, mostly with the CF (del Negro *et al.*, 1980). Main manifestations of chronic adrenal insufficiency are malaise, fatigue, anorexia, weight loss, arterial hypotension, orthostatic hypotension, hyperpigmentation of the skin, nausea, and reduced libido. The glands contain multiple granulomatous foci, and diffuse necrosis may be seen in the most severe cases. Hyperplasia of the adrenal glands also occurs commonly (Tendrich *et al.*, 1991). The adrenal insufficiency has been documented in patients even after prolonged post-therapy follow up (Tabón *et al.*, 1995), although in a few patients the adrenal function has been reported to fully recover (do Valle *et al.*, 1993).

Reports on the frequency of CNS involvement are quite variable, from 3.4% to 25.45% (Almeida, 2005); it is however more frequent than it has been admitted in the past. NeuroPCM (Fig. 8) should always be considered in the differential diagnosis of meningoencephalitis and in expansive processes of the CNS, especially in endemic areas (de Almedia *et al.*, 2004). Most patients with neuroPCM have the CF and involvement of other organs (particularly lungs) at the time SNC symptoms manifest. Involvement of the CNS is considered to be secondary to a primary focus: not infrequently the pulmonary involvement is diagnosed after that of the CNS. Rarely it is the sole localization of the disease (Almeida, 2005). A review showed that while in 21% of the cases the onset of neurological symptoms occurred before the onset of systemic symptoms, in 33% they happened simultaneously and in 46% they appeared after the onset of the systemic symptoms (de Almedia *et al.*, 2004). Pseudotumoral lesions in the brain hemispheres is the most typical presentation, although it can occur in any location of the CNS (Gasparetto *et al.*, 2003; Rosa Junior *et al.*, 2019). Clinical manifestations are non-specific and related to the location of the CNS lesion: according to a review, seizure in 33%, hemiparesis in 25%, cerebellar signs in 25%, headache in 21%, and hydrocephalus in 21%; less frequent symptoms include paresthesia in 13%, confusion in 13%, and bulbar signs in 8% (Almeida, 2005). CT scan images are usually hypodense, with annular or nodular enhancing, surrounded by mild edema after contrast injection. In 65% of the patients, there were multiple mass lesions, and 35% had a single mass lesion (Almeida, 2005). Meningitis associated with pseudo tumoral lesions can also occur. It usually presents as a skull base meningitis, with mild to moderate lymphomononuclear pleocytosis and elevated protein levels, but the finding of yeast cells in the CSF is an exception. Neuro-PCM is a serious condition: in a case series of 24 neuroPCM patients (de Almedia *et al.*, 2004), four patients died while 20 responded to the antifungal treatment, but most remained with residual lesions after treatment, characterized in the CT scan as hyperdense lesions, with irregular contrast enhancement, eventually residual calcified lesions. Neurological sequels are not uncommon in these patients.

Reports of septic shock caused by septicemia by *Paracoccidioides* spp. show that fungemia can occur (Azulay *et al.*, 1988; Londero *et al.*, 1996). However, probably death is not caused by the fungemia per se, but by the severely dysregulated immune response triggered by it which culminates in an inflammatory cytokine storm and extensive tissue necrosis (Benard *et al.*, 2010, 2012b).

Association between human immunodeficiency virus (HIV) infection and PCM has been reported (Benard and Duarte, 2000; Morejón *et al.*, 2009; Almeida *et al.*, 2017). PCM was also diagnosed occasionally in patients with other immunosuppressive conditions such as malignancies, transplant, and immunosuppressive therapies (Shikanai-Yasuda *et al.*, 2008; Ruiz e Resende *et al.*, 2015; de Almeida *et al.*, 2019). The number of cases in HIV-infected patients was much lower than it was initially expected from what was observed with the association of other systemic mycoses with HIV (e.g., histoplasmosis). However the actual number of cases may be underestimated since PCM still is not a compulsory notification disease in most endemic countries. Clinical manifestations of these patients often do not fit into the A/SAF or CF patterns. They frequently present a disseminated disease, with lymph nodes involvement, hepatosplenomegaly and cutaneous lesions, suggestive of the A/SAF, concomitant with pulmonary and/or oropharyngeal mucosal involvement, more frequently seen in the CF (Benard and Duarte, 2000; Morejón *et al.*, 2009; Almeida *et al.*, 2017). The likely explanation is that the disease is due to reactivation of a latent infection as in the CF, but with higher lymphohematogenous dissemination due to the immunosuppression, as seen in the A/SAF. In fact, most patients were living in urban areas when they developed the (Benard and Duarte, 2000; de Almeida *et al.*, 2019). Thus the proposition of the classification as mixed form. Most patients with HIV-PCM had CD4 cell counts below 200 cells/mL (Benard and Duarte, 2000; Morejón *et al.*, 2009; Almeida *et al.*, 2017; de Almeida *et al.*, 2019). Mortality was higher than in non-HIV infected, but it was usually attributed to other HIV-infection related comorbidities than to PCM itself (Morejón *et al.*, 2009; Almeida *et al.*, 2017; de Almeida *et al.*, 2019).

Treatment

Several classes of drugs can be used to treat PCM. Historically sulfonamides were the first class of compounds to be effective in the treatment of PCM (Ribeiro, 1940), followed by the introduction of amphotericin B in 1958 (Lacaz and Sampaio, 1958). Imidazole derivatives were introduced in the end of 1970s' with ketoconazole. This drug is now rarely considered in PCM treatment, having been replaced in the end of the 1980s' by the triazole derivative itraconazole (Negroni *et al.*, 1987; Restrepo *et al.*, 1987). Fluconazole is another option for PCM treatment, but is has less often been used for its lower in vitro activity compared with itraconazole, although it can be indicated for neuro-PCM cases for its low binding to plasma proteins, allowing diffusion into the CSF (Diaz *et al.*, 1992; Shikanai-Yasuda, 2015). Voriconazole, posaconazole, and isavuconazole showed inhibitory activity in vitro against *Paracoccidioides* spp. isolates and, therefore, are potentially useful in the treatment of PCM. These as yet high cost drugs are not easily accessible in the endemic areas. Thus, except for two pilot studies showing voriconazole and isavuconazole effectiveness against PCM, mostly in CF patients without severe disseminated disease, accumulated experience with these drugs is still lacking (Telles *et al.*, 2007; Thompson *et al.*, 2016). Voriconazole was used at 8 mg/Kg/day dose, usually 200 mg PO two times daily, while isavuconazole was used at 200 mg PO 3 times daily for 2 days followed by 200 mg once-daily (Telles *et al.*, 2007; Thompson *et al.*, 2016). Drug interactions and adverse events of prolonged therapy (as required for PCM treatment) may be issues with these drugs.

Until recently there was no consensus on treatment decisions and protocols: these varied considerably among reference centers, for several reasons. Total duration of therapy is quite variable according to the severity of the disease and the patients' clinical, radiological and serologic responses to treatment. Neither the classification of the severity of the disease nor the local availability of antifungal drugs are equal among the reference centers. There are scarce comparative studies on PCM treatment, most of them bearing important limitations (Queiroz-Telles *et al.*, 1992; Shikanai-Yasuda *et al.*, 2002; Borges *et al.*, 2014; Cavalcante *et al.*, 2014). A *quasi-experimental* study of 177 patients showed the superiority of itraconazole over the association of sulfamethoxazole and trimethoprim (SMX-TMP), the most commonly used drugs for PCM treatment in Brazil (the country that contributes with over 80% of the cases worldwide) (Cavalcante *et al.*, 2014). These studies nevertheless support the indication of itraconazole as the first-choice treatment for PCM. However, there are some situations in which SMX-TMP is preferred, including patients with neuro-PCM (itraconazole does not cross the blood brain barrier), and patients with gastrointestinal tract involvement, as itraconazole already has erratic absorption in the gastrointestinal tract (Shikanai-Yasuda, 2015). SMX-TMP may be a viable option for the treatment of severe disseminated life threatening PCM in cases amphotericin deoxycolate is contraindicated or lipid formulations are not accessible. An updated guideline on the management of PCM has recently been published by Brazilian experts (Shikanai-Yasuda *et al.*, 2017).

One of the major issues in the treatment of PCM is compliance for the patients often require at least one year of therapy. This issue is sibling of the other major issue in PCM, the development of sequels after treatment in a sizable proportion of patients, discussed in the next section. A retrospective study of SMX-TMP therapy in a poor resource endemic area showed that only 68.3% of 244 treatment records that fulfilled the study's inclusion criteria reported adequate compliance. However, this proportion is likely an overestimation because from the other 283 patients' records that did not fulfill the inclusion criteria, in 67.8% this was due to the patient's missing more than 50% of the appointments (Nery *et al.*, 2017). In fact, a recent study from another reference center in the same poor resource area reported a compliance rate of only 44.6% (Andrade *et al.*, 2019). The importance of continuous treatment must always be emphasized because relapses and increasing risk to developing sequels occur if the drug is not taken regularly. As the CF is strongly associated with smoking habit and alcohol abuse (Martinez and Moya, 1992; dos Santos *et al.*, 2003), particular care should be provided to these issues, in order to assure better compliance, better response to treatment, and lower risk of developing sequels (especially pulmonary damage).

Itraconazole is administered in 100 mg capsules that should be given short after a meal. The Brazilian guidelines recommend 200 mg/day for low to moderate severity forms (Shikanai-Yasuda *et al.*, 2017). Several groups reported good results with this therapy but relapses may still occur (Marques, 2002; Shikanai-Yasuda, 2015). However, we have now successful experience in treating patients with the more severe forms (either A/SAF and CF) of the disease with higher doses of itraconazole (400–600 mg/daily) provided

there is such an involvement of the digestive tract that could further impair the variable absorption rate of the drug. (amphotericin B, the conventional choice for these severe cases, has been reserved to patients with life threatening conditions). Absorption is also impaired by antacids or inhibitors of gastric acid secretion. Side effects have been few and include transient elevation of hepatic enzymes (Naranjo *et al.*, 1990; Shikanai-Yasuda, 2015). Itraconazole in children is recommended at a dose of 5–10 mg/kg daily, with a maximum dosage of 200 mg twice daily (Shikanai-Yasuda *et al.*, 2017).

SMX-TMP (400 mg/80 mg per tablet) is widely used in Brazil, mainly because of its easier availability within Brazil's public health system than itraconazole (Shikanai-Yasuda *et al.*, 2017). It has also been used in association with amphotericin B (Marques *et al.*, 1985). It has good absorption with predictable serum levels, as well as good tolerability, with myelotoxicity (leukopenia) the main side effect, which can be monitored and controlled by folic acid administration without modification of the therapeutic regimen (Telles *et al.*, 2007). Interstitial nephritis manifested as hyperkalemia may occasionally occur. The Brazilian guideline recommends 8–10 mg/kg of trimethoprim daily (Shikanai-Yasuda *et al.*, 2017). However, in adults it is given generally at a dose of two tablets PO at 12-h (low to moderate cases) or 8-h (moderate to severe cases) intervals with good results. This combination has the advantage of permitting alternative parenteral administration whenever necessary; in this case it can be administered from 12 to up 6-h intervals. Duration of the treatment with this drug varies in each case, but it usually lasts for no less than nine months. Maintenance treatment can be achieved by using one tablet at 12-h intervals. Development of SMX-TMP resistance is occasionally clinically suspected but has rarely been documented in vitro. There is a single report of resistance of an isolate from an A/SAF patient (Hahn *et al.*, 2003).

Amphotericin B should be reserved for severe disseminated or life threatening cases (Shikanai-Yasuda *et al.*, 2017). It also can be used by patients who relapse during the course of or after treatment with orally administered drug because gastrointestinal involvement may impair drug absorption in these cases. The effectiveness of therapy with azoles has curtailed the need for more aggressive regimens. There is still scarce data regarding effectiveness of the new amphotericin B lipid formulations. However, a series of 28 severe patients treated with amphotericin B lipid complex showed good results in all cases (Peçanha *et al.*, 2016).

Fluconazole is an alternative treatment, although not as effective at least in vitro. High doses, up to 600 mg/day, and longer treatment periods that itraconazole should be considered. Recrudescence and relapse of disease apparently occur more frequently than when itraconazole is used (Diaz *et al.*, 1992). Fluconazole may be useful in severely ill patients who must be treated intravenously (Shikanai-Yasuda, 2015). No experience with the A/SAF has yet been reported.

Aids patients can be treated initially intravenously with amphotericin B or SMX-TMP IV (800/160 mg thrice daily), then moved to itraconazole 400–600 mg/day or SMX-TMP P.O. 800/160 mg thrice daily. Alternatively, patients may also be treated orally with higher doses of itraconazole (400–600 mg/day) or SMX-TMP (800–160 mg PO or IV at 12 8-h intervals). Good therapeutic response is generally observed, achieving control of the PCM. Treatment can be moved to the lower regular doses of both drugs until the TCD4+ counts reach 200 cells/ μ L (or eventually at least 100 cells/ μ L), provided the HIV viral load remains undetectable (Shikanai-Yasuda *et al.*, 2017). Pharmacological interaction with antiretroviral drugs is an important issue to be addressed in the treatment of Aids patients. For more details regarding treatment of specific conditions such as HIV-infection, pregnancy, children severe forms, the reader is referred to the Brazilian guidelines (Shikanai-Yasuda *et al.*, 2017).

Many issues remain to be addressed regarding optimal treatment of PCM. As stated earlier, treatment of PCM still faces many challenges such as the low compliance rates and strategies that could curtail the development of sequels. The role of adjunct therapy with immunomodulators, such as peptides derived from the *P. brasiliensis* immunodominant glycoprotein that act by augmenting the Th-1-mediated immune responses, was tested in vivo in experimental models only (Taborda *et al.*, 2015). A few studies demonstrated some in vitro reactivity of patients' T-cells to these peptides (Leo *et al.*, 2007). Further studies are required to demonstrate their utility in promoting protective cell mediated immune responses in the human host. In the opposite direction, some investigators have administered short courses of corticosteroids as adjunct therapy to severe cases, based on the rationale that some patients suffer from an uncontrolled or excessive inflammatory response (Gryschek *et al.*, 2010; Benard *et al.*, 2012a). In support of this, some fatalities were attributed to the exacerbated inflammatory response (Benard *et al.*, 2010, 2012b). Patients who benefited from adjunct prednisone administration (0.5–1.0 mg/kg) for 1–2 weeks were those with intense inflammation in CNS, obstructive lesions of the larynx or trachea, lung lesions resulting in respiratory insufficiency and unremitting fever and weight loss (Gryschek *et al.*, 2010; Benard *et al.*, 2012a). The clinical and laboratory criteria that allow reduction in the antifungal dose or that could be used to end treatment with the assurance that the patient is cured are not established. Progressive decrease in the titers of the serologic tests currently available is one of the laboratory parameters used most frequently. Newer methods (e.g., antigenemia detection, proteomic biomarkers) still need further standardization and clinical studies and have not yet become widely available (Gómez *et al.*, 1998; Salina *et al.*, 1998; Marques da Silva *et al.*, 2003; Marques Da Silva *et al.*, 2004; Sylvestre *et al.*, 2018). Meanwhile, most specialists agree that treatment decisions need to be tailored according to the patient. Table 1 includes the first line drugs recommended in the therapy of PCM.

Prognosis

Prognosis depends on the status of the patient at the time of diagnosis. Children and adults in whom fungemia has taken place and who have multiple organ involvement may respond less well to therapy and require critical care. Fatality rate due to PCM is progressively being reduced as a result of earlier diagnoses and better treatments. In a report describing eight deaths in a cohort of 141 pediatric cases, fatality rate was 9.5% in the 1981–2001 period and 2.6% in the 2002–2019 period (Romanelli *et al.*, 2019). As stated

Table 1 First line drugs recommended for therapy of PCM

Drugs	Administration	Treatment schedule
Itraconazole	Adult: 200 mg/day Children 5–10 mg/kg/day	For ≥ 9 months of treatment. In adults and adolescents the 200 mg dose can be reduced to 100 mg/day with clinical/mycological cure and low antibodies titers in serological tests
SMX-TMP	Adult: SMX 800 mg/TMP 160 mg (PO 8/8 or 12/12hs) children 5MX 40–50 mg/Kg / TMP 8–10 mg/kg (PO 12/12hs)	For ≥ 9 months of treatment. In adults and adolescents the dose can be reduced to 400/160 mg/Kg PO 12/12hs with clinical/mycological cure and low antibody titers in serological tests
Amphotericin B	deoxycholate 0.5 to 0.7 mg/kg/day (IV) lipid formulation 3–5 mg/kg/day (IV)	Attack treatment for few (usually 2–4) weeks then move to itraconazole or SMX-TMP

Note: Adapted with modifications from Shikanai-Yasuda, M.A., *et al.*, 2017. Brazilian guidelines for the clinical management of paracoccidioidomycosis. *Revista da Sociedade Brasileira de Medicina Tropical*, 50 (5), 715–740. doi:10.1590/0037-8682-0230-2017.

earlier, albumin level on admission could be a predictor factor for death. Other authors indicated that abdominal complications, especially liver involvement, ascites and malnutrition, were associated with the lethal prognosis (Nogueira *et al.*, 2006; de Melo Braga *et al.*, 2013). In the A/SAF, mortality rates are lower. Complete remission is to be expected for most but not all patients with the A/SAF and CF since sequels may develop and certain organ involvements may be definitive (e.g., pulmonary fibrosis, adrenal insufficiency, neurological sequels). Thus, some clinicians consider the term *cure* inappropriate because of the inability to confirm complete eradication of the organism; the term *apparent cure* should instead be used (Shikanai-Yasuda *et al.*, 2017).

PCM persists as a disease with relatively low mortality but considerable morbidity. Complications vary and, like prognosis, their occurrence depends on the extent of fungal invasion. In the A/SAF, early complications that may lead to surgical intervention are intestinal obstruction and jaundice, both of which result from enlarged mesenteric lymph nodes, or emergency tracheostomy due to laryngeal lesions leading to tracheal stenosis. Sequels are more common in adults than children. In general, fibrosis is the cause of serious problems in patients who respond to therapy, particularly when extensive pulmonary infiltrates are present. Despite the newer, very effective therapies, these sequelae preclude, in a proportion of the cases, the complete restoration of the patients' previous health status (Tobón *et al.*, 2003; Lopera *et al.*, 2015). Scarring and fibrosis of the affected nodes and residual pulmonary fibrosis have been noted in earlier studies (Londero *et al.*, 1996). A study showed that almost all recently treated CF patients remain with at least one abnormality on CT scan (Costa *et al.*, 2013), the most frequent of which were architectural distortion, reticulate and septal thickening, centrilobular and paraseptal emphysema and parenchymal bands. These findings likely reflect the pattern of dissemination of the fungi through the lymphatics and subsequent fibrosis previously described in histopathology studies (Tuder *et al.*, 1985). Functionally, patients typically presented with a mild obstructive disorder and a mild reduction in diffusion capacity with preserved exercise capacity. However, one third of patients presented significant oxygen desaturation upon exercise that was associated with respiratory distress (Costa *et al.*, 2013). In addition, centrilobular and paraseptal emphysema were also observed in most patients, reflecting the high tobacco exposure in this population, and emphasizing the importance of tobacco exposure cessation for better treatment results. A recent study of post-treatment patients with a longer follow-up showed persistence of the fibrosis and emphysema abnormalities; all patients were smokers (Pina, 2006). Attempts to reduce post-treatment pulmonary fibrosis have been tested in experimental models only but may be promising (Lopera *et al.*, 2015). Rarely, a patient may remain with significant enough fibrous scarring to result in development of cor pulmonale (Campos *et al.*, 1986). Other important sequels that may be present in the CF are hoarseness, tracheal stenosis leading to definitive tracheostomy, microstomia, which requires surgical reconstruction, adrenal insufficiency, which requires long life hormonal replacement, and neurological sequels (do Valle *et al.*, 1995; Tabón *et al.*, 1995; Londero *et al.*, 1996; Weber *et al.*, 2006; Francesconi *et al.*, 2011; de Pina *et al.*, 2018).

Human PCM has no recognized prophylactic treatment. Vaccine strategies are being developed but are still restricted to experimental models of the disease (Taborda *et al.*, 2015).

Vaccine Development

The antifungal treatment of PCM requires prolonged drug use plagued by relapses and fibrotic sequelae that incapacitate individuals. This lead scientists to look for new tools (reviewed by Taborda *et al.*, 2018; Shikanai-Yasuda *et al.*, 2017). In this sense, the use of prophylactic or therapeutic vaccines would be an option to protect the host or to reduce the treatment time (Travassos and Taborda, 2012).

One of the most promising vaccine studies concerns the P10 peptide, derived from the *P. brasiliensis* 43 kDa glycoprotein (gp43) (Taborda *et al.*, 1998).

The epitope was mapped to a 15-mer peptide (QTLIAHTLAIRYAN), immunodominant and protective in murine models against a virulent isolate of *P. brasiliensis*. This effect was attributed to a strong cellular immune response mediated by the secretion of IFN- γ and IL-2 (Travassos and Taborda, 2012). Very importantly, P10 is also immunodominant and promiscuous in PCM patients, being recognized by 9 predominant HLA molecules, thus becoming a promising candidate for an effective vaccine against PCM in humans (Iwai *et al.*, 2003).

An interesting approach was carried out aiming at associating the P10 peptide with antifungal chemotherapy. Treatment of mice (anergic or not) with antifungal drugs such as itraconazole and sulfamethoxazole/trimethoprim plus P10 showed a protective reduction of the fungal load in the lungs, preserving the alveolar structure and preventing the spread of the fungus to the spleen and liver (Travassos and Taborda, 2012). Based on the peptide P10, different vaccine models with anergic or immunocompetent mice were developed involving: dendritic cells (Magalhães *et al.*, 2012; Silva *et al.*, 2017, 2019); hepatitis B virus-derived particle (VLP) as an antigen carrier (Holanda *et al.*, 2017); Different adjuvants such as aluminum hydroxide, flagellin, cationic lipid dioctadecyl-dimethylammonium bromide (DODAB) and complete Freund's adjuvant (CFA) (Mayorga *et al.*, 2012; Braga *et al.*, 2009); P10 incorporated into PLGA (Amaral *et al.*, 2010), etc.

DNA Vaccine

A vaccine against *P. brasiliensis* using plasmid DNA was first tested in 2000 (Pinto *et al.*, 2000) with a mammalian expression vector carrying the full gene of the gp43 under the control of CMV promoter with Freund's adjuvant resulting in the induction of both B and T cell-mediated immune responses, modulated by IFN- γ . This immunization method was protective in mice prior to challenge with virulent *P. brasiliensis*. Similar DNA vaccines were carried out using P10 as the minigene in the plasmid construction (Pinto *et al.*, 2000).

When given prior to or after infection with a *P. brasiliensis* virulent isolate, plasmid-vaccination with P10 successfully reduced the fungal burden in lungs of infected mice. Intramuscular injection of a combination of plasmids expressing P10 and IL-12 given weekly for one month, followed by single injections, restored normal lung architecture and eradicated the fungus in mice infected one month before treatment (Rittner *et al.*, 2012).

Mice immunized with another plasmid carrying the P10 minigene (pcDNA3-P10) were examined, before and after infection with *P. brasiliensis*, for the expression of memory CD4 + CD44^{hi} T cells together with Foxp3 + Treg cells in the spleens and lungs, post infection. Both T lymphocyte types increased corresponding to a lung histopathology with minimal inflammation. The repeated immunization with the.

DNA-P10 plasmid which generated long-term memory and regulatory T cells, replaced the initially protective pro-inflammatory T effector cells, and were thus effective while preserving the integrity of the infected tissue (de Amorim *et al.*, 2013).

Other researchers have also studied different vaccine models such as: DNA vaccine based on HSP65 from *Mycobacterium leprae*, rPb40 and rPb27 recombinant proteins in association with fluconazole reviewed by (Rossi *et al.*, 2019), radio-attenuated yeast cells (Demicheli *et al.*, 2006).

Antibodies

Clinical studies showed that patients with paracoccidioidomycosis develop antibodies, although only a few of them are protective against the mycosis reviewed by (Boniche *et al.*, 2020). Therapy based on passive transference of monoclonal antibodies showed efficient anti-fungal activity in an experimental model using mice. de Mattos Grosso *et al.* (2003) demonstrated that monoclonal antibodies against a 70 kDa glycoprotein of *P. brasiliensis* protected mice infected with the fungi (de Mattos Grosso *et al.*, 2003). Buissa-Filho *et al.* (2008) showed protective and non-protective monoclonal antibodies against gp43, the main diagnostic antigen of *P. brasiliensis* (Buissa-Filho *et al.*, 2008). Other protective antibodies were described: anti-melanin polyclonal antibodies obtained by immunization of mice with melanin ghosts of *P. brasiliensis* reduced fungal burden (da Silva *et al.*, 2006); monoclonal antibodies generated against heat shock protein 60 from *H. capsulatum* also reduced fungal burden from mice infected with *P. lutzii* (Thomaz *et al.*, 2014), polyclonal antibodies to acidic glycosphingolipids (GSL) purified from *P. brasiliensis* reduced infection (Bueno *et al.*, 2016). The results showed that passive transference of antibodies can be a therapeutic strategy associated or not with antifungal chemotherapy.

Acknowledgments

We would like to thank Ronaldo C. B. Gryscek for critical review of the chapter and Thalyta Nery C. Pinto for preparing the Fig. 5. Sporotrichosis

Rodrigo Almeida-Paes, Maria C Gutierrez-Galhardo, and Rosely M Zancopé-Oliveira, Oswaldo Cruz Foundation, Rio de Janeiro, Brazil

Introduction

Sporotrichosis is a subcutaneous mycosis with a worldwide distribution, especially in tropical and sub-tropical areas. The infection generally occurs by a traumatic inoculation of an organic matter containing the fungus into the subcutaneous tissue of humans or other susceptible animals. After a few days, lesions appear, commonly affecting the skin and the lymphatic vessels draining to the nearest lymph node (Barros *et al.*, 2011). Apart from fulfilling the criteria to be considered a neglected disease, its emergence in last years has called public health attention in countries of tropical and subtropical regions (Queiroz-Telles *et al.*, 2017).

This chapter will present topics regarding the state of art of the etiological agents of sporotrichosis, including their taxonomic classification, morphology, biology, ecology, and virulence, as well as sporotrichosis epidemiology, clinical presentations, pathogenesis, diagnosis, and treatment.

The Genus *Sporothrix*

The genus *Sporothrix* comprises more than 50 different species of fungi that can cause disease on plants, insects, and animals, including humans (de Beer *et al.*, 2016). All these species are eukaryotic heterotrophic organisms, have no mobility, and present a chitin-containing cell-wall (Barros *et al.*, 2011).

The Human Pathogenic *Sporothrix* Species

Since the first description of human sporotrichosis in the last years of the 19th century (Schenk, 1898) until the beginning of the 21th century, the single species described as an agent of human sporotrichosis was *Sporothrix schenckii* (Lopes-Bezerra *et al.*, 2006). However, after the advent of molecular biology, some studies based on DNA analysis demonstrated a high level of genetic variability among *S. schenckii* strains from different regions and from different clinical presentations of the disease (Liu *et al.*, 2003; Marimon *et al.*, 2006). In 2007, phenotypic and genotypic analyzes revealed that *S. schenckii* should not be considered the only etiologic agent of sporotrichosis (Marimon *et al.*, 2007). Since then, cases of *Sporothrix* infection in humans have been related to at least six species besides *S. schenckii*: *Sporothrix brasiliensis* (Almeida-Paes *et al.*, 2014), *Sporothrix globosa* (Madrid *et al.*, 2009), *Sporothrix luriei* (Marimon *et al.*, 2008), *Sporothrix mexicana* (Dias *et al.*, 2011), *Sporothrix pallida* (Morrison *et al.*, 2013), and *Sporothrix chilensis* (Rodrigues *et al.*, 2016). All these species are classified into the phylum Ascomycota, subphylum Pezizomycotina, class Sordariomycetes, order Ophiostomatales, family Ophiostomataceae (Guarro, 2012).

Morphology and Dimorphism

All *Sporothrix* species that cause sporotrichosis in humans are dimorphic fungi, that is, in the environment or under laboratory conditions at 25–30°C present a mycelial (or filamentous) morphology and during animal infections and when cultivated at 35–37°C in enriched culture media, such as brain heart infusion agar or blood sheep agar a yeast-like morphology is observed (Barros *et al.*, 2011).

Macroscopically, the colonies of these fungi in the mycelial form are initially white and glabrous, but after some days (usually three to ten, depending on the species and strain phenotypic characteristics), they usually develop a wrinkled and membranous aspect, and start to darken, turning brown to black in color (Fig. 1(A)). These colonies are composed by hyaline, septate, thin hyphae with sympodial thin-walled hyaline conidia and sessile thick-walled brown-to-black conidia (Fig. 1(B)). The color of the colony is related to the amount of dematiaceous conidia produced by the fungus. Thus, some strains that can not produce these structures, remain white, even after months of laboratory cultivation (Almeida-Paes *et al.*, 2015). The dematiaceous conidia may have specific formats depending on the species. For instance, *S. brasiliensis* produce globose to subglobose conidia, whereas *S. schenckii* conidia are triangular to cuneiform (Marimon *et al.*, 2007). However, this is not a specific taxonomic characteristic, since conidial morphology may present some variation among strains from a single species (Oliveira *et al.*, 2012a).

The transition to the mycelial to yeast form is an adaptive process to the host environment that is depending on the activation of some signaling pathways after *Sporothrix* spp. senses the higher temperature and different nutrient conditions of the host (Boyce and Andrianopoulos, 2015). Colonies on enriched media incubated at 35–37°C are white-to-creamy in color and have a smooth to wrinkled texture (Fig. 2(A)). The yeast-like cells of the human pathogenic *Sporothrix* species are ovoid with single, double, or in rare occasions, multiple buds (Fig. 2(B)). These cells often have a “cigar-shaped” feature, an aspect that is usually used to characterize the genus. (Barros *et al.*, 2011).

Fig. 1 Morphology of the mycelial form of *Sporothrix* spp. (A) Macroscopic aspect of a *Sporothrix brasiliensis* colony on PDA medium, 20 days of incubation at 30°C; (B) Slide culture of a *S. brasiliensis* strain after 20 days of incubation at 30°C, stained with Lactophenol Cotton Blue. Straight arrow indicates hyaline conidia and dashed arrow indicates dematiaceous conidia.

Fig. 2 Morphology of the yeast-like form of *Sporothrix* spp. (A) Macroscopic aspect of *Sporothrix brasiliensis* colonies on BHI agar medium, 7 days of incubation at 37°C; (B) Lactophenol cotton blue stain of *S. brasiliensis* yeasts after 7 days of incubation at 37°C.

Up to now, structures related to sexual reproduction in all *Sporothrix* species that cause infections in humans are unknown. However, genomic analyzes demonstrate that at least *S. schenckii* and *S. brasiliensis* have the potential for sexual reproduction, since they present a MAT locus in the genome, as well as mitogen-activated protein kinase pheromone pathway, pheromone processing enzymes, and meiotic regulators (Teixeira *et al.*, 2015).

Fungal Biology and Ecology

The physiological features of the human pathogenic *Sporothrix* species vary among the different species and morphologies of the fungi. Regarding growth conditions, the mycelial form of the fungus is more tolerant to basic pH, whereas yeasts are more adapted to grow in acidic conditions (Ghosh *et al.*, 2002). Optimum growth temperature is around 20–30°C, with the growth of all species impaired at 40°C. However, despite the ability to cause infections in the human host, the species *S. globosa* has low thermotolerance and the growth of most strains is inhibited at temperatures around 35°C (Marimon *et al.*, 2007). *Sporothrix* spp. have tolerance to both osmotic pressure and high salt concentrations, especially in the parasitic yeast form (Ghosh *et al.*, 2002) and tolerate cycloheximide concentrations up to 0.25% (Barros *et al.*, 2011).

Several carbon sources such as glucose, fructose, glycerol, maltose, sorbitol, trehalose, mannose, xylitol, and cellobiose can be assimilated, but not fermented. Inositol and lactose are not assimilated. Differences among species and even among strains from the same species are observed in the assimilation of sucrose, arabinose, rhamnose, raffinose, starch, and ribitol (Ghosh *et al.*, 2002; Marimon *et al.*, 2007). All species can produce urease at least in one fungal morphology (Almeida-Paes *et al.*, 2015; Ghosh *et al.*, 2002). Iron acquisition, which is indispensable during parasitism, occurs through the reductive pathway (Zarnowski and Woods, 2005) and through hydroxamate siderophore production (Holzberg and Artis, 1983).

As the majority of human pathogenic fungi, the agents of sporotrichosis live in the environment as organic matter decomposers. They release a series of enzymes that break down the decaying material, producing small subunits that can be absorbed by

the fungal cells. Infection in a mammal host is not necessary to *Sporothrix* spp. to complete their life cycle, that is, human parasitism is accidental. The agents of sporotrichosis can be found in cellulose-rich soils with high humidity, plants, water, decaying wood, among other outdoor environments (Barros *et al.*, 2011). The most traditional environmental sources of human pathogenic *Sporothrix* species are rose thorns, *Sphagnum* moss, cornstalks, and hay. Despite their association with plants, these species were never described as plant pathogens, growing better on dead wood (Chakrabarti *et al.*, 2015).

Putative Virulence Factors

More than 50 different species are described in the genus *Sporothrix* (de Beer *et al.*, 2016), and the number of new species in this genus is continuously increasing (Ngubane *et al.*, 2018). However, only seven of them have been described as potential agents of disease in humans and other mammals. Moreover, the majority of sporotrichosis cases are caused only by three species: *S. brasiliensis*, *S. globosa*, and *S. schenckii* (Chakrabarti *et al.*, 2015). These species should have evolved differently from others in order to survive when accidentally come into a warm-blooded host.

The most accepted theory to explain the origin of virulence in *S. schenckii* and in the other human pathogenic species is the resistance that they developed against environmental stressors such as extreme pH, temperatures, and water availability, as well as presence of high salinity, radiation, and chemical pollution (Téllez *et al.*, 2014). Moreover, *Sporothrix* environmental interactions with other organisms, such as soil amoeba and bacteria, may have triggered the development of survival strategies that can be also used by the fungus during parasitism (Almeida-Paes *et al.*, 2017, 2019; Steenbergen *et al.*, 2004). As a result of this microbial interaction, the pathogenic species of *Sporothrix* gathered some putative virulence factors that facilitate survival when the fungus accidentally is inoculated into the host. These virulence factors include the dimorphism ability, thermotolerance, cell-surface adhesins, melanin production, and secreted hydrolytic enzymes (Ruiz-Baca *et al.*, 2015).

The Disease

Epidemiology

Epidemiological sporotrichosis data is usually strongly biased because this is not a notifiable disease in most countries, with most information about the disease coming from case reports and case series, which are only a “tip of the iceberg” of the sporotrichosis problematics.

Sporotrichosis usually is a benign disease, although some sporotrichosis-related deaths are reported in the literature. Some countries reporting sporotrichosis as a cause of death in humans include Brazil, the United Kingdom, and the United States of America (Kugblenu and Reeves, 2016; Moreira *et al.*, 2015).

Sporotrichosis had a high incidence in France in the beginning of the 20th century, but nowadays it is an uncommon disease in Europe. Sporotrichosis currently presents a considerable endemicity in Brazil, China, Colombia, India, Japan, Madagascar, Mexico, Peru, South Africa, Uruguay, and Venezuela (Chakrabarti *et al.*, 2015). Differences are also observed in the frequency of the sporotrichosis agents among these countries: while *S. brasiliensis* prevails in Brazil and is emerging in Argentina, *S. schenckii* is the main sporotrichosis agent in other countries of the Americas and Africa, and *S. globosa* is more frequent in Asia (Chakrabarti *et al.*, 2015; Córdoba *et al.*, 2018; Rasamoelina *et al.*, 2019).

All sexes and individuals of any age are equally affected by *Sporothrix* spp. Local peculiarities on sex/age characteristics of sporotrichosis cases are associated to the risk factors for fungal exposure in different regions. In general, sporotrichosis is an occupational disease that mostly occurs in gardeners, miners, and farmers, who are individuals handling or working closely to any organic matter where the fungus can be present. More recently, people handling possible infected animals, such as veterinarians, pet caretakers, hunters, and fishermen are also a high-risk sporotrichosis group (Barros *et al.*, 2011).

Epidemics of sporotrichosis are usually associated with a common source of infection (Bustamante and Campos, 2001). The largest sporotrichosis epidemic related to environmental *Sporothrix* exposure occurred in Witwatersrand, South Africa between 1941 and 1944. In this epidemic, thousands of miners were infected by *S. schenckii* present in the wood logs used in the mines. The miners presented pustular ulcerative, papular, plaque or warty skin lesions. This epidemic ended after the treatment of the mine timbers with a fungicidal spray to kill the fungus present in the surface of the wood (Helm and Bermam, 1947).

The major sporotrichosis epidemic in the United States of America, occurred in 1988, affected 84 patients in 15 states. The environmental source associated to these cases was the *Sphagnum* moss used for reforestation purposes (Coles *et al.*, 1992). A smaller outbreak involved contact of five patients with hay bales in a Halloween haunted house. Other point-source outbreaks of sporotrichosis were reviewed in this work, revealing that hay bales, haystacks, moss and straw were the potential sources of infection, and duration of exposure to these sources varied from a few minutes to six weeks (Dooley *et al.*, 1997).

Some hay-related epidemics have also been reported in Australia (Conias and Wilson, 1998; Dhingra *et al.*, 2015). In China, outbreaks involving young children with facial lesions are usually associated with decaying cornstalks stacked for cooking and heating during cold seasons (Song *et al.*, 2011). In Peru, where sporotrichosis affects more children than adults, the most common risk factors for this mycosis are the ownership of a cat, activities in crop fields, dirt floor in the house, outdoors work, ceilings made of raw wood, and low socioeconomic status (Lyon *et al.*, 2003).

Fig. 3 Lymphocutaneous sporotrichosis in the right arm of a male patient.

In Brazil, since 1998, an increasing number of sporotrichosis cases are observed in human patients infected by the scratch, bites, or contact with naturally *Sporothrix* infected cats (Gremião *et al.*, 2017). In this country, middle-aged homemakers, retired elderly, and young students of deprived social strata are the major at-risk groups, due to their contact with domestic cats. In Rio de Janeiro state, where this zoonotic epidemic started in the late 90's, the number of cases increased continuously for more than 20 years (Gutierrez-Galhardo *et al.*, 2015), with more than 10,000 human cases diagnosed up to 2019. Other Brazilian states have less cases of this disease, however, a spread of zoonotic sporotrichosis through the Northeast and West parts of the country have been observed in last years (Arantes-Ferreira *et al.*, 2019; Lacerda-Filho *et al.*, 2019).

Zoonotic sporotrichosis occurs in other places, such as Argentina, Australia, Germany, India, Japan, Malaysia, Mexico, Panama, Peru, Spain, and the United States of America, but always with a much lower incidence than Brazil (Gremião *et al.*, 2017; Ramírez-Soto, 2016; Rios *et al.*, 2018). In Thailand, sporotrichosis in a cat was also reported, highlighting that zoonotic sporotrichosis may be also occurring in this country (Duangkaew *et al.*, 2019). An important aspect among some of these areas is that *S. brasiliensis* is the major agent in Brazil (Gremião *et al.*, 2017), whereas *S. schenckii* is involved in feline cases from Asia (Han *et al.*, 2017).

Clinical Presentations

The lymphocutaneous form is the most common presentation, accounts for more than 75% of cases and is the easiest form of sporotrichosis to diagnose. The lesions are usually located on the upper extremities. A primary lesion appears at the site of inoculation after two or three weeks, which corresponds to the chance of inoculation. According to the time of evolution, this lesion can be ulcerated with an infiltrated base or a papular, nodular, nodular-ulcerative, ulcerative-gummy or vegetative plaque. From the initial injury, a chain of painless nodules, known as sporotrichoid spread, forms along the path of the lymph vessels (Fig. 3). These nodules may soften and ulcerate with some exudate. Usually, the regional lymph nodes are not involved, and no skin changes are observed between the nodes (Barros *et al.*, 2011).

The fixed cutaneous form is the second most common clinical presentation and accounts for approximately 20% of cases. The lesion remains confined to the inoculation site and the lymph vessels are not involved. It is believed to occur due to prior sensitization of the individual to the fungus which results in better host immune control, thereby limiting the lesion. The lesions are ulcers, verrucous, infiltrative, or ulcero-infiltrative plaques (Fig. 4). Small satellite lesions are common. This clinical form tends to be more chronic. The upper and low extremities are the most common sites of lesions, but the face, neck and trunk are affected as well (Barros *et al.*, 2011).

The disseminated cutaneous form is characterized by multiple skin lesions at noncontiguous sites without extracutaneous involvement. They tend to be more extensive than lesions from other cutaneous forms and cystic abscess can also be observed (Fig. 5). This form is rare and is caused by hematogenous spread of the fungus, usually associated with immunosuppression (Barros *et al.*, 2011; Moreira *et al.*, 2015). However, disseminated cutaneous sporotrichosis has been more frequently observed (up to 16% of cases) during endemic zoonotic sporotrichosis. In these cases, the involvement of non-immunosuppressed patients has been attributed to multiple inoculations by domestic cats (Barros *et al.*, 2011; Chakrabarti *et al.*, 2015).

In extracutaneous sporotrichosis the lesions may be restricted to a single site (and are only locally progressive) or may be disseminated (multifocal disease). The osteoarticular system is the most frequent site of unifocal disease. It occurs by contiguity with skin lesion and/or by direct inoculation of the fungus. Systemic symptoms are minimal. Osteomyelitis, isolated or with arthritis, may be present with or without skin lesions. The most commonly affected bones are the tibia, the small bones of feet and hands, the radius, the ulna, the skull and the face. Patients may present localized swelling and local sinus tract formation. The knee is the most common affected joint, but hand, elbow, and ankle joints may also be involved. Similarly, tenosynovitis, isolated or associated with osteoarticular sporotrichosis, may appear. Failure to consider the diagnosis leads to a chronic course with sequel (Rex and Okhuysen, 2010; Lederer *et al.*, 2016).

Fig. 4 Fixed cutaneous sporotrichosis in the right hand of a female patient.

Fig. 5 Disseminated cutaneous sporotrichosis in a male patient.

Primary lung disease occurs after inhalation of *Sporothrix* conidia and is usually associated with chronic obstructive pulmonary disease. The patient may be asymptomatic or have respiratory symptoms, and the radiological pattern of chronic cavitary disease is observed (Rex and Okhuysen, 2010; Aung *et al.*, 2013).

Ocular sporotrichosis is usually related to zoonotic transmission through direct inoculation into the eye of secretions from naturally infected cats. Granulomatous conjunctivitis, eyelid sporotrichosis, and dacryocystitis are the most common presentations (Fig. 6). Parinaud oculoglandular syndrome (granulomatous conjunctivitis and satellite adenomegaly) is also frequent. Sequelae such as chronic dacryocystitis and fistulas are observed. Children are particularly affected by ocular sporotrichosis probably due to ludic contact with cats (Barros *et al.*, 2011; Freitas *et al.*, 2014a; Arinelli *et al.*, 2019).

Disseminated extracutaneous (multifocal) disease is associated with immunosuppressive conditions such as HIV infection, use of corticosteroids or other immunosuppressive drugs, diabetes, alcoholism, neoplasms, and organ (especially kidney) transplants.

Fig. 6 Ocular sporotrichosis: bulbar conjunctivitis and lesion at the left upper eyelid.

Fig. 7 Erythema nodosum associated with sporotrichosis in a female patient.

This form occurs by hematogenous dissemination of the fungus to any organ or tissue. The symptoms are specific to the involved organ and are followed by fever and general commitment in some cases. In addition to skin involvement, multifocal osteoarticular disease (mainly in the feet and hands), lung, central nervous system, and mucosae (ocular and upper airway), can be affected (Gutierrez-Galhardo *et al.*, 2010; Rex and Okhuysen, 2010). The radiological pattern of pulmonary involvement is diffuse reticulonodular infiltrate, with symptoms similar to those occurring in primary pulmonary disease, except for hemoptysis. Central nervous system involvement is characterized by chronic subacute meningitis or brain abscess, and isolation of *Sporothrix* spp. from the cerebrospinal fluid may be difficult. Hydrocephalus is a common and potentially serious complication in these cases. In intraocular sporotrichosis due to hematogenous dissemination, anterior or posterior uveitis, choroiditis, retinal granuloma and/or endophthalmitis are observed (Gutierrez-Galhardo *et al.*, 2010; Rex and Okhuysen, 2010). The mucosa of the mouth, pharynx, larynx, and nose can be infected by both direct and hematogenous routes. Enanthema, ulceration, suppuration, and vegetation are the clinical manifestations observed. Signs and symptoms may include rhinorrhea, nasal obstruction,odynophagia, and dysphagia. Endocarditis is also reported (Silva-Vergara *et al.*, 2012).

In endemic countries for sporotrichosis, disseminated sporotrichosis may be the initial manifestation of HIV/AIDS. In the same way, patients with sporotrichosis who start antiretroviral treatment may experience worsening of pre-existing lesions or the emergence of new lesions characterizing an immune reconstitution syndrome (Freitas *et al.*, 2012a, 2014b).

The recognition of new *Sporothrix* species of clinical interest (Marimon *et al.*, 2007) has raised an important issue, among others, concerning the clinical and therapeutic relevance for the new taxonomy of the sporotrichosis agents. *S. brasiliensis* has been associated with hypersensitivity reactions, specifically in the region of Rio de Janeiro, Brazil, where this species has been highly implicated. These include erythema nodosum (Fig. 7) (Gutierrez-Galhardo *et al.*, 2002), erythema multiforme (Gutierrez-Galhardo *et al.*, 2005), Sweet syndrome (Freitas *et al.*, 2012b) and reactive arthritis (Barros *et al.*, 2011; Orofino-Costa *et al.*, 2017). A trend in the association of this species with disseminated disease in patients without an immunosuppressive underlying cause has also been observed, as well with greater severity, causing hospitalizations and deaths especially in aids

patients (Almeida-Paes *et al.*, 2014). Meanwhile, *S. globosa*, the most prevalent etiologic agent of sporotrichosis in China, is more associated with localized forms of the disease (Marimon *et al.*, 2007; Zhao *et al.*, 2017).

Pathogenesis

The broad range of clinical manifestations observed in sporotrichosis is the consequence of interactions between fungal and host cells. The host response depends on the site of infection, the infective *Sporothrix* species, the fungal morphotype (conidia, yeast-like cells), and the immunological status of the host. This response usually begins with an innate recognition of *Sporothrix* spp. by toll-like receptors (TLR) or by an inflammasome-dependent pathway, which modulates the subsequent adaptive immune response that basically consists in a mixed Th1/Th17 pattern (Gonçalves *et al.*, 2017).

Phagocytosis driven by macrophages, dendritic cells, and neutrophils constitute the first line of host defense against *Sporothrix* spp. After phagocytosis, these cells promote fungal antigen processing, production of reactive oxygen and nitrogen species, and antigen presentation, which lead to the inflammatory response. Yeast-like cells of *Sporothrix* spp. have the ability to escape the respiratory burst generated by the phagocytes through ergosterol-peroxide production, by the protection conferred by some components of the fungal cell-wall and by the several types of melanin produced by the fungus (Almeida-Paes *et al.*, 2015; Carlos *et al.*, 2015). More recently, an early role of defense involving natural killer cells in sporotrichosis has been proposed. These cells have a pivotal role in the *in vivo* elimination of *S. schenckii* due to their immunoregulatory role (Ferreira *et al.*, 2018).

Granuloma formation is another process of the host defense and a critical event in the immune response against members of the genus *Sporothrix* (Miranda *et al.*, 2013). Besides intact polymorphonuclear cells, granulomas present in tissues of patients with sporotrichosis normally contain caseous material, cellular debris, giant and epithelioid cell lymphocytes, plasmocytes, fibroblasts, and fungal yeast cells within phagocytes or in the extracellular medium (Barros *et al.*, 2011). The *Sporothrix* melanin has a role in the formation of granulomas. While heavily-melanized strains induce formation of multifocal granulomas, melanin-deficient strains remain restricted to the core of a unifocal granuloma (Almeida-Paes *et al.*, 2015).

Cellular immunity is the main response against *Sporothrix* spp. T CD4 cells were long recognized as pivotal in specific sporotrichosis immunity (Tachibana *et al.*, 1999). More recently, it was demonstrated that during *S. schenckii* systemic experimental mice infection, Th17 and Th1/Th17 mixed cells are developed, leading to an augmented production of IL-17 and IL-22. The Th17 response is necessary for fungal clearance (Ferreira *et al.*, 2015). A differential cellular immunity occurs between different *Sporothrix* species. For instance, *S. brasiliensis* induces a sustained Th17 and regulatory T cell responses, which contribute to a more severe disease than *S. schenckii* (Batista-Duarte *et al.*, 2018).

Specific antibodies against *Sporothrix* spp. are produced after IL-4 stimulation. It occurs in advanced stages of sporotrichosis, usually after four to six weeks post infection. Since patients with different clinical forms of sporotrichosis present similar pattern and amount of specific antibodies against *Sporothrix* spp., these molecules probably do not play a crucial role in sporotrichosis pathogenesis, though being useful for diagnostic purposes (Barros *et al.*, 2011). A role for antibodies in sporotrichosis was proposed, where *S. schenckii* yeast-cells opsonized by specific immunoglobulins are more efficiently killed by macrophages, which produce high TNF- α levels (Franco *et al.*, 2012).

Diagnosis

Although the clinical manifestations of sporotrichosis are well described, the definitive diagnosis of this mycosis cannot be based solely on these manifestations, since they can be mistaken with manifestations of other diseases, and differential diagnosis is mandatory. Lymphocutaneous sporotrichosis is fairly common and can be confidently clinically diagnosed. However, pyoderma, atypical *Mycobacterium* sp. and *Nocardia* infection as well as leishmaniasis must also be considered. The clinical symptoms of the fixed form can be similar to pyoderma, paracoccidioidomycosis, chromoblastomycosis, cutaneous tuberculosis, atypical mycobacteria, tertiary syphilis, leishmaniasis, and even skin cancer. Lesions of the disseminated cutaneous form can be confused with other deep mycosis (paracoccidioidomycosis, cryptococcosis, or histoplasmosis), atypical mycobacteria, or noninfectious granulomatous diseases. The disseminated extracutaneous forms are differentially diagnosed according to the affected organ. Other fungal conjunctivitis, bacterial, viral or fungal meningitis, bacterial osteomyelitis, pulmonary fungal infections, tuberculosis, and sarcoidosis should be considered (Rex and Okhuysen, 2010; Orofino-Costa *et al.*, 2017).

Sporotrichosis is classically diagnosed through the association of clinical, epidemiological, and laboratory data. For the diagnosis of cutaneous forms, the material must be obtained from the most recent lesions. In the evaluation of extracutaneous forms, the approach for isolation of the etiological agent will depend on the affected site. In lesions on conjunctival, nasal and oral mucosa, a swab should be collected for mycological examination. Evaluation of otolaryngologist and ophthalmologist with upper digestive airway endoscopy and ophthalmoscopy, respectively, are important. In cases of pulmonary sporotrichosis, chest X-rays should initially be requested and, if altered, chest CT and sputum examination for fungal screening. In the osteoarticular form, the most indicated exams are radiography, computed tomography (CT) or, if available, magnetic resonance imaging of the affected segment. If sporotrichosis in the central nervous system is suspected, a cranial CT scan should be request to rule out expansive lesions and to guide lumbar puncture for cerebrospinal fluid evaluation (mycological, biochemical and cytological examination). In patients with HIV infection, and CD4 T cell counts lower than 350 cells μL^{-1} should have sputum, urine, blood, and cerebrospinal fluid mycological tests, as well as imaging (chest X-ray, sinus CT), ophthalmoscopy, endoscopy and bone scintigraphy tests.

Fig. 8 Direct examination of samples positive for sporotrichosis. (A) Potassium hydroxide slide examination of a skin biopsy from a cat with naturally acquired sporotrichosis. (B) Gram stain of a lesion exudate smear from a human patient with lymphocutaneous sporotrichosis. Arrows in both panels indicate yeast-like fungal cells. Bars: 10 μm .

Mycological examination comprises the direct examination and culture tests. Direct examination is usually performed with potassium or sodium hydroxide, to detect cigar-shaped budding yeast cells of 2–6 μm diameter (**Fig. 8(A)**). These cells are hard to detect in samples from immunocompetent human patients or most animals, but can be found in samples from immunosuppressed patients and cats with sporotrichosis (**Barros et al., 2011**). Gram and Giemsa stains can help in the visualization of *Sporothrix* yeast-like cells (**Fig. 8(B)**).

The definitive diagnosis of sporotrichosis is based on the isolation and identification of its etiological agent in culture. It is usually performed on Sabouraud Dextrose Agar with chloramphenicol 400 mg L^{-1} to prevent bacterial contamination, and on a cycloheximide-containing culture medium, to inhibit the growth of anemophilous fungi that may grow in the cultures of clinical specimens obtained from non-sterile sites (**Orofino-Costa et al., 2017**). Cultures should be incubated at 25–30°C, and must be screened at least once a week for a minimum of four weeks to detect the growth of filamentous fungi with a compatible morphology with *Sporothrix* spp. Traditional identification of these colonies are performed through the study of the macroscopic and microscopic characteristics of the colony, previously described in this chapter, both on mycelial and yeast forms. These analyzes, however, do not differentiate the species within the genus. The gold-standard method for *Sporothrix* species identification is the partial sequencing of the calmodulin gene (**Marimon et al., 2007**). In last years, other methodologies to differentiate the *Sporothrix* species have been described, including qualitative and quantitative polymerase chain reaction (PCR) with specific primers, PCR fingerprinting, rolling circle amplification, random fragment length polymorphism of the calmodulin gene, and matrix-assisted laser desorption/ionization using time-of-flight mass spectrometers (**Oliveira et al., 2012b, 2015; Orofino-Costa et al., 2017**).

Positive *Sporothrix* cultures provide the definitive evidence for the diagnosis of sporotrichosis, but this procedure has some limitations. It is difficult to obtain a suitable clinical specimen for culture in some disease manifestations, such as *Sporothrix*-induced arthritis (**Barros et al., 2011**). In addition, cultures often present false-negative results due to low fungal burden, antifungal use, or contamination with bacteria and/or non-pathogenic fungi (**Oliveira et al., 2019**). To overcome these limitations, non-culture

diagnostic methods have been developed to improve diagnostic sensitivity and quickness. The results of these tests provide a presumptive diagnosis of sporotrichosis and require clinical correlation for the correct assessment and determination of the final diagnosis (Barros *et al.*, 2011).

The most used non-culture diagnostic method for sporotrichosis is the detection of specific anti-*Sporothrix* antibodies in serum samples. Precipitation and agglutination techniques were first used, but these tests lack sensitivity in cases of cutaneous sporotrichosis and do not determine the isotype of immunoglobulins involved in the response (Barros *et al.*, 2011). The use of immunoblot and, more frequently, enzyme-linked immunosorbent assays (ELISA) to substitute these tests has increased in endemic areas in the last years. Together, culture and ELISA tests can vastly diagnose sporotrichosis, with a combined high sensitivity (Oliveira *et al.*, 2019).

So far, few molecular methods have been applied to detect *Sporothrix* DNA from clinical samples. Some PCR-based protocols targeting the large subunit ribosomal ribonucleic acid, chitin synthase, and calmodulin genes show a high level of specificity and are promising tools for sporotrichosis diagnosis (Barros *et al.*, 2011).

Treatment

Although spontaneous regression of lesions can occur in sporotrichosis (Lopes-Bezerra *et al.*, 2006), treatment is generally necessary (Barros *et al.*, 2011). Despite the existence of non-pharmacological treatments such as surgical excision, cryosurgery, thermotherapy, and photodynamic therapy, the use of antifungal drugs is the most widely used therapeutic strategy for this mycosis (Orofino-Costa *et al.*, 2017).

Potassium iodide has traditionally been used to treat sporotrichosis since the beginning of the last century, with satisfactory results. Some authors suggest that the saturated solution of potassium iodide (SSKI) acts on the resolution of granulomas by increasing proteolysis, while others claim that it promotes an increase in phagocytosis. However, the exact mechanism of action remains unknown to this day. The SSKI is still one of the most prescribed drugs for the treatment of cutaneous sporotrichosis, due to its effectiveness and low cost. SSKI is initially administered at five drops, three times daily, and gradually increased, as tolerated, to 40–50 drops, three times daily. The dosage for children is one drop, three times daily, and increased as tolerated up to 1 drop kg⁻¹ (maximum of 40–50 drops), three times daily (Kauffman *et al.*, 2007). Recently, lower doses of potassium iodide for the sporotrichosis treatment were proposed, with satisfactory results (Barros *et al.*, 2011; Orofino-Costa *et al.*, 2017).

The azoles act inhibiting ergosterol synthesis by fungal cells. Itraconazole 100–200 mg once a day is currently the treatment of choice for sporotrichosis. This drug has a great *in vitro* activity against the major sporotrichosis agents and a cure rate up to 94% (Barros *et al.*, 2011; Kauffman *et al.*, 2007). Fluconazole is less effective than itraconazole and it is not a good therapeutic option. Ketoconazole, in addition to greater toxicity, has not shown good response in human infection (Kauffman *et al.*, 2007). Voriconazole appears to be modest in *S. schenckii* cases and ineffective against *S. brasiliensis* (Fernández-Silva *et al.*, 2014). Posaconazole is effective against several *Sporothrix* species and has a good therapeutic response, even in cases of disseminated disease (Paixão *et al.*, 2015). Its use in the treatment of sporotrichosis remains to be assessed.

In cases of contraindications to itraconazole, terbinafine (250–500 mg once a day) is the most reliable option, with a good cost-effectiveness. Amphotericin B is reserved for extracutaneous cases and pregnant women who have disseminated disease. Pregnant women are a difficult group of patients to treat, since potassium iodide, itraconazole, and terbinafine are not indicated. If possible, they should not receive any drug treatment until the end of pregnancy (Kauffman *et al.*, 2007). Thermotherapy and cryosurgery have been used successfully to treat cutaneous forms of sporotrichosis during pregnancy (Ferreira *et al.*, 2012; Fichman *et al.*, 2018).

The antifungal treatment should be offered until the clinical cure of the patient (reepithelization of the lesions, absence of erythema, infiltration, and crusts) that occurs around 12 weeks (Barros *et al.*, 2011; Francesconi *et al.*, 2011). Hypersensitivity reactions should be treated with prednisone (40 mg per day) for short or medium periods.

Conclusions and Perspectives

Sporotrichosis is a disease that meets the criteria to be named as a tropical neglected disease. The advances in the taxonomy of the sporotrichosis agents and the emergence of this mycosis occurring in several countries brought much knowledge on this topic, but progress in some areas are still missing. For instance, there is a lack of rapid, commercially available tests to diagnose the infection. In addition, no vaccines are available and endemic countries do not have public health actions to curb the disease expansion. Translational research is urgently needed to improve the health outcome of this neglected disease.

Introduction

Pneumocystis species are harbored in mammalian lungs where they exist in sub-clinical numbers or may cause a lethal pneumonia in mammalian hosts that have weakened immune systems. Once thought to be protozoan parasites or fungi, these organisms were definitively identified as members of the fungal kingdom with the advent of genomic sequencing. The genus *Pneumocystis* belongs to subphylum *Taphrinomycotina* of phylum *Ascomycota* (Redhead *et al.*, 2006, Chabe *et al.*, 2011). These host-specific obligate fungi are typically restricted to the lungs, though reports of extrapulmonary cases have not been infrequent (Ng *et al.*, 1997; Sharma *et al.*, 2019; Kim *et al.*, 2018). The five described species and their mammalian hosts include *P. carinii* and *P. wakefieldiae* in rats; *P. murina* in mice; *P. oryctolagi* in rabbits and *P. jirovecii* in humans. The challenge of Pneumocystis research has been the lack of an *in vitro/ex vivo* growth system, which impacts almost all experimental approaches including gene knockouts to assign function, evaluation of drug efficacy and resistance, and assessment of its full life cycle (Sinai *et al.*, 2012).

The proposed life cycle mostly takes place in the lung, with bi-phasic modes of asexual replication via binary fission by trophic forms (1–4 µm) and a sexual cycle initiated by two mating types resulting in an ascus with eight spores (5–8 µm) (Hauser and Cushion, 2018) (Fig. 1). To complete the life cycle, the infection is transmitted via an airborne mode with final deposition of asci in the alveoli of the next host(s). The second extra-pulmonary phase is the release of the propagule (presumably the ascus) from the infected host to complete the life cycle in the next host. Genomic and functional analyses support primary homothallism as the mechanism for sexual reproduction with each trophic form carrying the genes encoding both mating types (Almeida *et al.*, 2015; Richard *et al.*, 2018) (described in more detail below). Self-fertility being a sound strategy for a host-obligate pathogen.

Fig. 1 Putative life cycle of *Pneumocystis*. (A) Airborne asci have been proposed to be the agent of infection. After inhalation, the spores ultimately take residence in the terminal portion of the respiratory tree, the alveoli. Neither the mechanism of migration to the alveoli nor the form in which the organism arrives in the alveoli (intact ascus or individual spores) are known. (B) Sexual phase: Two presumptive mating types conjugate (B1), undergo karyogamy (B2), and produce a diploid zygote (B3) that progresses through meiosis to produce four haploid nuclei (B4) followed by an additional mitosis to produce eight nuclei (B5). The nuclei are packaged into spores by invagination of the ascus cell membranes (B6) to produce eight double-membrane spores (B7). The ascus can undergo excystment via a protuniculate release by unknown mechanisms (B8) or exit out of the lungs (B9). The spores released in the lung can then undergo asexual (C) or sexual (B) replication with a presumed opposite mating type. (C) Asexual phase: Haploid trophic forms are thought to replicate asexually by binary fission, whereby the nuclear content is duplicated (C1) along with cellular contents that divide into two haploid trophic forms (C2). The mechanism of exit out of the lung (D) is unknown. The figure of life cycle was adapted with modifications from Cushion, M.T., 2010. Are members of the fungal genus *pneumocystis* (a) commensals; (b) opportunists; (c) pathogens; or (d) all of the above? *PLoS Pathogens* 6 (9), e1001009. doi:10.1371/journal.ppat.1001009 and used under the Creative Commons Public Domain declaration; the human image was obtained from Getty Images 165564540 with credit to Leonello Calvetti.

Table 1 Current status of the sequenced *Pneumocystis* genomes in the NCBI

Organism	Strain	Type of genome	Number of genes/ORFs	Database accession IDs
<i>P. carinii</i>	B80	Nuclear	3646	LFVZ01
	N/A	Mitochondrial	17	NC_013660/JX499145
<i>P. murina</i>	B123	Nuclear	3623	AFWA02
	N/A	Mitochondrial	15	NC_020332/JX499144
<i>P. jirovecii</i>	RU7	Nuclear	3761	LFWA01
	SE8	Nuclear	3537	CAKM01
	E2178	Nuclear	N/A	NJFV01
	N/A	Mitochondrial	14	NC_020331/JX499143

Pneumocystis Genomes

With the advent of high-throughput sequencing, such as whole genome shotgun sequencing (WGS), and advanced software tools for assembly, genomes of select *Pneumocystis* species were obtained; for those most relevant for laboratory experiments (rodent models of *Pneumocystis* pneumonia – *P. carinii* and *P. murina* from rats and mice, respectively) and clinical studies (the species infecting humans – *P. jirovecii*). The mitochondrial genome of *P. carinii* was first reported (Sesterhenn *et al.*, 2010) followed by those of *P. murina*, *P. jirovecii* and a re-sequenced version of *P. carinii* (Ma *et al.*, 2013). Of note, while both rodent pathogens have linear mitochondrial genomes, the human species was found to have a circular structure. Following an initial report of a transcriptional profile of *P. carinii* during fulminant pneumonia (Cushion *et al.*, 2007), more complete assemblies of nuclear genomes and transcriptomes of these fungi were reported (Cisse *et al.*, 2012; Ma *et al.*, 2016). Table 1 summarizes the current availability of *Pneumocystis* genomes in the NCBI Genome database.

Ultra-deep pyrosequencing targeting two nuclear genomic regions: ITS2 (internal transcribed spacer 2) and DHFR (dihydrofolate reductase), and one mitochondrial DNA region – mtLSU (the mitochondrial ribosomal RNA large subunit gene) in 25 PCP patients revealed that 92% patients were infected with a mixture of *Pneumocystis* strains (Alanio *et al.*, 2016). This suggests prior therapies used and/or multiple sources of reinfection may dictate the variability of the infecting pathogens, and consequently presents a challenge in defining a treatment regimen while facing various drug susceptibilities of the pathogen populations.

Ploidy

The study of ploidy was reported for *P. carinii* only, based on high-throughput cytometry (Martinez *et al.*, 2011). Most trophic forms contained haploid genomes, but diploid trophic forms were also present though less abundant. The DNA content of cysts (asci) suggests each ascus bears eight spores containing haploid genomes. Of note was the presence of forms with 4C and 3C content, but in much fewer numbers than the 1C and 2C stages. The variability in the overall trophic size and sizes of their nuclei is dramatically illustrated in the ultramicrograph shown in Fig. 2. The occurrence of life cycle stages with these nuclear contents may indicate that meiotic replication (4C) is a rapid or relatively rare event while the 3C genomes indicate ploidy variation is not an uncommon event in fungi which could arise from diploid:haploid mating or asymmetric mitotic division (Martinez *et al.*, 2011).

Comparative Genomics

Comparison of the *Pneumocystis* genomes may reveal how the pathogen coevolved with its mammalian hosts, and by comparing these genomes with those from other phylogenetically related but free-living fungi could shed light on metabolic strategies of these fungal pathogens with an obligate parasitic life style. In the past decade, at least three major studies were published where *Pneumocystis* species were compared among themselves and with *Schizosaccharomyces pombe*, *Taphrina deformans* (both are from the same subphylum as *Pneumocystis* spp.) and a well-studied model fungal organism *Saccharomyces cerevisiae* (Hauser *et al.*, 2010; Porollo *et al.*, 2014; Ma *et al.*, 2016).

Genes Absent From the Genome

Hauser and colleagues noted a dramatic underrepresentation of the enzymes needed for the amino acid biosynthesis in *P. carinii* compared to baker's yeast, suggesting that the pathogen has to scavenge amino acids from the host lung environment (Hauser *et al.*, 2010). While that study supported the notion of the parasitic life style of the pathogen, it did not help cultivate the organism *ex vivo*, as all culture medium formulations used in the field have abundant amounts of all natural amino acids. A biotrophic life style was first proposed in an earlier study of the transcriptome of *P. carinii* (Cushion *et al.*, 2007) and supported by later studies employing comparative genomics (Hauser, 2014; Cisse *et al.*, 2014). Porollo and colleagues expanded comparative genomic analyzes to all three sequenced *Pneumocystis* species and compared them with the genome of the fission yeast, *S. pombe* (Porollo *et al.*, 2014). While confirming the lack of amino acid biosynthesis pathways, as well as a previously noted incomplete ergosterol biosynthesis pathway (Kaneshiro, 2004; Joffrin and Cushion, 2010), they

Fig. 2 Variation in nuclear and overall cell size of trophic forms. Transmission electron micrographs of *Pneumocystis carinii* trophic forms in rat lungs. Note the variation in size of mid-sized (A), small (B) and large trophic forms (MTC, personal collection).

also found over-representation of inositol metabolism compared to the fission yeast. Subsequent supplementation of culture media with *myo*-inositol significantly increased viability of *P. carinii* using an *in vitro* short-term cell-free culture compared to un-supplemented controls, but still did not enable continuous growth. Ma and colleagues pushed the field further and made, perhaps, the most comprehensive comparative analysis of the genomes (and partial transcriptomes) of *P. murina*, *P. carinii*, *P. jirovecii*, *T. deformans*, *S. pombe*, and *S. cerevisiae*, by going beyond the analysis of their metabolism (Ma *et al.*, 2016). The latter study outlined major strategies that the *Pneumocystis* species evolved to adapt to the obligate parasitic life style as well as to evade the host immune system. Overall, the *Pneumocystis* genomes are much smaller, with reduced gene sets, compared to the free-living fungi.

It should be noted that these results are likely to be further refined. Such comparative studies heavily rely on the sequence homology-based annotation of the genomics sequences. Despite the constant growth of reference databases, *Pneumocystis* species remain challenging in terms of functional annotation of their genes. Only a small fraction of their genes is annotated with high confidence. Moreover, such genome-wide annotations may yield inconsistent results between research groups, depending on what bioinformatics tools and reference sequence databases are used. As an illustration, Ma and colleagues posited that there are no inositol transporters present in the *Pneumocystis* genomes (Ma *et al.*, 2016). Yet, Porollo and colleagues first suggested candidate genes for these transporters shared among all three organisms (Porollo *et al.*, 2014) and subsequently demonstrated their function and ligand specificity (Fig. 3; Cushion *et al.*, 2016).

Dramatic reduction or complete loss of enzymes required for *de novo* biosynthesis of many critical nutrients suggests an adaptation of *Pneumocystis* organisms to the obligate parasitic life style when majority of these compounds are scavenged from the host (Cushion and Stringer, 2010). Such nutrient acquisition strategy assumes a wide range of genes encoding various transporters. In this regard, the published reports are again contradictory. Cisse and colleagues suggest that up to 22% genes in *Pneumocystis* genomes encode transporters, *e.g.*, amino acid permeases (Cisse *et al.*, 2012). Ma and colleagues, in contrast, report significant reduction of plasma membrane transporters (Ma *et al.*, 2016). As illustrated by the contradictory findings of the *myo*-inositol transporters, we hypothesize that the latter research group might have used very stringent criteria for their sequence homology search that lowered the sensitivity of their bioinformatics approach to gene annotation.

The complexity of experimental annotation of *Pneumocystis* genes impedes a large-scale functional characterization of the pathogen genome, at least until a continuous *ex vivo* growth system is established for these fungal pathogens. Until then, researchers in the field will have to rely on bioinformatics approaches and databases of better annotated organisms. Fortunately, both are being constantly improved.

Select Genomic Features of *Pneumocystis*

Sexual replication

Even though the life cycle of *Pneumocystis*, including the mechanisms of transmission, are still not fully understood (Skalski *et al.*, 2015), there is mounting evidence that sexual reproduction is an obligate step for the growth and transmission of these fungi (Cushion *et al.*, 2010; Hauser and Cushion, 2018). Moreover, genomic analysis revealed all mating type genes (MAT) located in one conserved region across *Pneumocystis* species on one chromosome thereby suggesting that these organisms use primary homothallism for sexual

reproduction (Almeida *et al.*, 2015). Homothallism appears to be very common in fungi (Sun *et al.*, 2019). It may help explain the observation of multiple strains coexisting in the same host as noted in the previous section.

Major surface glycoprotein superfamily

While all *Pneumocystis* genomes are dramatically reduced in size compared to free living fungi, there is a notorious enrichment of the major surface glycoproteins (Msg) and related genes. This family of genes share structural similarities, are located at the telomeric ends of all chromosomes, and most use a single site for expression (Cushion and Stringer, 2010). This superfamily of genes are unique to the *Pneumocystis* species as sequence homology searches have not identified any homologs in other organisms in the NCBI non-redundant protein database (Delaye *et al.*, 2018). With improvements in both sequencing methodology and assembly software, the complexity of this family suggested in earlier studies is being confirmed and expanded (Schmid-Siegert *et al.*, 2017; Delaye *et al.*, 2018; Ma *et al.*, 2016). As an illustration, the genome of a *P. jirovecii* strain assembled from a long-read sequencing approach using a bronchoalveolar lavage fluid (BALF) specimen from a single patient yielded 113 Msg genes (Schmid-Siegert *et al.*, 2017). Another study reported 64–179 unique Msg genes per each sequenced *Pneumocystis* species (Ma *et al.*, 2016). The Msg superfamily in *Pneumocystis* spp. is currently comprised of five families of glycosylphosphatidylinositol-anchored glycoproteins and one family of secreted glycoproteins (Schmid-Siegert *et al.*, 2017). The Msg proteins appear to have conserved domains but otherwise highly variable sequences likely due to gene conversion (Keely and Stringer, 2009; Vink *et al.*, 2011; Delaye *et al.*, 2018). These translocations may be facilitated by the lack or paucity of introns in the Msg genes, repetitive elements or meiotic hot spots comprised of G + C rich regions (Cushion and Stringer, 2010; Delaye *et al.*, 2018). Very few microbes can survive in the lower airways of a healthy host and antigenic variation is a strategy used by fungi and protozoa alike. It was recently suggested that the Msg genes have an accelerated rate of evolution due to their intimate interactions with the host species (“biotic interactions”), fulfilling the “Red-Queen Hypothesis” (RQH) (The RQH has its origins in a statement made by the Red Queen to Alice in Lewis Carroll’s *Through the Looking-Glass* while in Looking-Glass Land (“Now, here, you see, it takes all the running you can do, to keep in the same place”) and first used by Leigh Van Valen to describe evolutionary adaptation. Martin, Douglas (October 30, 2010). “Leigh Van Valen, Evolution Revolutionary, Dies at 76”. *The New York Times*).

The RQH contends that as the biotic environment of species is constantly evolving, in this case the mammalian lung, other species within the environment (*Pneumocystis*) must constantly adapt to the changing environment in a highly dynamic process (Delaye *et al.*, 2018). Besides immunological evasion, the other obvious function for these surface glycoproteins is adherence – both to host cells (predominantly Type I pneumocytes) and to each other. As shown in Fig. 2, trophic cells are tightly adherent, forming large clusters akin to biofilms in the alveoli. Not shown in the ultra-micrograph are intermediate life cycle stages and asci, which are also in these aggregates.

Drug Targets, Gene Polymorphism and Drug Resistance

Drug Resistance

Cotrimoxazole (TMP-SMX) is the primary option for the treatment and prophylaxis of PCP. *Pneumocystis* is required to synthesize its folates as it lacks any salvage genes, and this drug combination targets two enzymes in the folate pathway: dihydrofolate reductase (DHFR) and dihydropteroate synthase (DHPS). Targeted sequencing established significant risks of developing drug resistance by *Pneumocystis* via mutations in these two enzymes (Kazanjan *et al.*, 2000; Navin *et al.*, 2001; Visconti *et al.*, 2001; Costa *et al.*, 2003; Ponce *et al.*, 2017; Singh *et al.*, 2019a,b; Wang *et al.*, 2019). Heterologous systems based on *S. cerevisiae* expressing the *Pneumocystis* genes allowed for kinetic measurements of reduced inhibition rates in mutants compared to wild type controls (Iliades *et al.*, 2005; Cody *et al.*, 2009; Moukhliis *et al.*, 2010; Cody *et al.*, 2013; Queener *et al.*, 2013). Building on these kinetic data and covariance analysis of protein sequences, Porollo and colleagues proposed a prediction model for drug resistance that correlates well with the experimentally observed data (Baker *et al.*, 2016).

New Drug Targets and Therapies

Adverse reactions to TMP-SMX and concerns of the increasing incidence of drug resistant strains makes the search for new drug targets a priority of the research community. During the past decade, a wide range of potential targets were proposed. Such targets are listed in Table 2.

Fig. 3 Isomer and sugar specificity of myo-inositol transport in *P. carinii*. Substrate specificity of *P. carinii* inositol transporter (PcITR1) was tested using the competitive uptake assay. (A) Isomer specificity - myo-inositol vs. 11 other inositol isomers and derivatives. (B) Sugar specificity - myo-inositol vs. 14 common natural sugars. Concentrations of 0.5 μ M myo-[2-3H] inositol and 100 $\times$ the unlabeled inositol isomers and sugars were used. Data are expressed as percentages of the results for the PBS control (no competitor). Data are the average results from 5 separate analyses. Error bars show standard deviations. Significance was determined by the paired-sample two-tailed *t* test. **P* < 0.05; ****P* < 0.001. Figure was adapted from Cushion, M.T., Collins, M.S., Sesterhenn, T., *et al.*, 2016. Functional characterization of *Pneumocystis carinii* inositol transporter 1. *mBio* 7 (6), doi:10.1128/mBio.01851016.

Table 2 New drug targets for anti-PCP treatment

Target	Function	Reference
AdoMet transport (PET8)	Facilitates scavenging of the host S-adenosylmethionine (AdoMet)	Perez-Leal <i>et al.</i> (2011)
Histone acetyltransferase (Rtt109)	Acetylation of histone H3 lysine 56 (H3K56) for maintenance of genome integrity and DNA damage repair; conserved in fungi but absent in humans	Dahlin <i>et al.</i> (2014)
<i>myo</i> -inositol transporter (ITR1)	Transport of <i>myo</i> -inositol, the only mechanism to obtain this essential molecule	Porollo <i>et al.</i> (2014), Cushion <i>et al.</i> (2016)
Dihydrofolate synthase (DHFS) and aminodeoxychorismate lyase (ABZ2)	Folate biosynthesis pathway	Luraschi <i>et al.</i> (2015)
APL5, COS111, MKK1, and STE2	Sphingolipid glucosylceramide (GlcCer) biosynthesis	Mor <i>et al.</i> (2015)
ACS2	acetyl coenzyme A (acetyl-CoA) synthetase	Koselny <i>et al.</i> (2016)
GSC1 and KRE6	Essential for 1,3- β - and 1,6- β -glucan biosynthesis; imparts rigidity to asci	Luraschi <i>et al.</i> (2017)
GFA1, GNA1, AGM1, and UDP-GlcNAc pyrophosphorylase (UAP1)	N-Acetylglucosamine biosynthesis	Kottom <i>et al.</i> (2017)

There have been several reports of therapy with the echinocandin, caspofungin, alone or in combination with trimethoprim-sulfamethoxazole or clindamycin (Jin *et al.*, 2019; Yang *et al.*, 2019; Zhang *et al.*, 2018; Li *et al.*, 2016) with inconsistent outcomes. The variability is likely due to a number of factors including co-morbidities, dosing, or severity of the pneumonia. Administration of echinocandin therapy remains controversial for treatment in humans (Luraschi *et al.*, 2019). In a systematic study of 3 echinocandins in a mouse model of PCP it was clear that these anti-fungal agents were effective at dramatically reducing the number of asci to undetectable numbers, but large burdens remained that were comprised of non-glucan expressing *P. murina* (Cushion *et al.*, 2010). Importantly, cessation of the echinocandin treatment after 3 weeks, with the immunosuppressive agent still present, permitted a return of asci to baseline numbers. These studies are a cautionary note to echinocandin monotherapy.

Conclusions and Future Directions

Although there has been substantial progress in understanding the genetic composition and its translation to present or absent metabolic pathways, much work remains to dissect these fungi. There is a notorious lack of strong homology for many *Pneumocystis* genes to sequenced genes in other organisms. It suggests either a strong influence of the mammalian hosts on pathogen to diverge so dramatically from the other members of its phylum, or an underdevelopment of the genome assemblers from the shotgun sequencing data followed by inaccurate gene prediction.

Decades of failing attempts to identify a silver bullet – a major single ingredient missing in the culture medium – to achieve a long-term culture of *Pneumocystis*, even after backing potential supplements with the analysis of metabolic pathways in the organism, may suggest at least two future directions in this area. One is to perform an unbiased analysis of the dynamic changes in a metabolite profile of the extracted pathogen, followed by flux balance analysis (FBA) to optimize the nutrient combination for culture media. Alternatively, cell-based approaches may be required for the *ex vivo* growth of these host obligate fungi and newer approaches such as alveolar epithelial cell- or lung organoid-based system may provide nutrients missing in the cell-free culture systems.

Introduction

Subcutaneous fungal infections consist of a group of mycoses involving the skin and the subcutaneous tissues, mainly occurring in tropical and subtropical countries. Some fungi may cause different diseases, according to their aspect in the infected tissue (Verma *et al.*, 2018). For instance, when some dematiaceous fungi appear in the tissue as muriform (or sclerotic) cells, the disease is chromoblastomycosis; when they form hyphae, the diagnosis is phaeohyphomycosis; when grains occur, the classification is eumycetoma. Other diseases are not mycoses but have historically been studied within this group due to former mistaken classifications, such as rhinosporidiosis (not covered here) and actinomycetoma. Since 2017, mycetoma, chromoblastomycosis and other deep mycoses are on the World Health Organization's (WHO) list of neglected diseases (WHO, 2017). Such inclusion brings an important aid to the visibility of these diseases and to the affected patients, implying more resources for their study, diagnosis and treatment optimization. Actions on education, information and prevention may reduce cases, especially considering that most of them are in developing countries. The constant migration around the globe makes the knowledge of this group of diseases fundamental for health care professionals. Sporotrichosis, one of the main mycoses within this group, is covered in another chapter.

Chromoblastomycosis

Also known as chromomycosis or Pedroso and Lane mycosis, chromoblastomycosis (CBM) has a chronic and progressive course. It was first scientifically published by Maximilliano Rudolph, in 1914. This mycosis can be caused by different genera of dematiaceous fungi, i.e., melanin producers. Some agents of CBM also cause other diseases, such as phaeohyphomycosis and eumycetoma (Queiroz-Telles *et al.*, 2017a).

Epidemiology

The overall burden of CBM is unknown, since it is not a notifiable disease, but its highest prevalence occurs in tropical and subtropical regions. CBM rarely occurs in children, and men between 40 and 50 years old are the most involved. The male: female ratio ranges from 5:1 to 9:1. As an occupational disease, it affects agricultural and forestry workers, gardeners and others exposed to contaminated plant material such as construction workers (Queiroz-Telles *et al.*, 2017a). In Brazil, the babassu coconut (*Attalea speciosa*) harvest was closely related to the disease, and in India it is linked to black tea cultivation in Assam and rubber plantations in Kerala and Western Ghats. Madagascar, Brazil, Mexico, Dominican Republic, Venezuela, India, and southern China report most of the cases (Agarwal *et al.*, 2017; Queiroz-Telles *et al.*, 2017a).

The disease is caused by fungi from the soil and plants, as saprobic decomposers of this organic matter. *Fonsecaea pedrosoi* is the most common pathogen in tropical areas. Recently, new species of this genus have been described: *Fonsecaea monophora*, *Fonsecaea nubica* and *Fonsecaea pugnacious* (de Azevedo *et al.*, 2015). In southern China, all reported cases are associated with *F. nubica*. *Phialophora verrucosa* is the second most prevalent fungus. *Cladophialophora carrionii* is the most important agent in dry and desert countries of Australia, South Africa and Cuba. *Rhinocladiella aquaspersa*, *Exophiala dermatitidis*, *Exophiala spinifera* and *Cladophialophora boppii* are uncommon agents. Recently, cases caused by *Cyphellophora ludoviensis* and *Rhinocladiella tropicalis* have been described (Gomes *et al.*, 2016).

There is usually a decrease in the number of cases following changes in agricultural methods, with the use of fungicides and mechanization (Queiroz-Telles *et al.*, 2017a).

Pathophysiology

The accidental contact of humans with the agents contributes to the onset of the mycosis, usually due to skin trauma and fungal inoculation. Within the tissue, the fungus converts its filamentous phase into thick brownish-walled globular structures, called muriform cells. These are rounded structures, and multiply by septation, in one or two planes, stimulating a granulomatous and purulent inflammatory reaction in its surroundings (Queiroz-Telles *et al.*, 2017a).

Clinical Features

The most frequently affected sites are the extremities of the lower limbs, followed by the upper limbs, gluteal region, trunk and face. The initial lesion, usually a papule, arises in the place of the previous trauma, not always noticed by the patient. This lesion can be single or multiple, with a slow growth and polymorphic (Queiroz-Telles *et al.*, 2017a).

Fig. 1 Chromoblastomycosis. Credits to Antonio Carlos Francesconi do Valle, MD PhD. (A) Verruciform and cicatricial plaques on the forearm of a woman. (B) Tumoral lesion on the leg of a man. (C) Verruciform and cicatricial extensive lesions on the inferior limb of a man. (D) Nodular plaque on the foot of a man.

According to Carrión, the initial lesions may evolve into five distinct clinical types: nodular, plaque, tumoral, verruciform and cicatricial (**Fig. 1**). The lesions are usually unilateral and insidious. The progression of a plaque may present central healing and ulceration. Other factors such as edema or secondary infection may modify the clinical presentation ([Carrión, 1950](#)).

The severity of the disease is classified by the number, extent and spread of the lesions. The mild form is represented by a solitary plaque or nodule smaller than 5 cm in diameter; the moderate form includes nodular, verrucous, single or multiple plaque lesions, affecting one or two adjacent regions, presenting less than 15 cm in diameter, and the severe form presents extensive lesions in adjacent or non-adjacent regions, including tumor and cicatricial types ([Queiroz-Telles et al., 2017a](#)).

The general clinical condition is not affected, but extensive injuries may interfere with physical capacity. Long-term lesions may have localized pruritus that may be mild or severe. Secondary infection, often frequent and recurrent, can cause pain, strong odor, fibrosis and chronic lymphedema. There may be contiguous spread to bones, causing osteolytic lesions. Neoplastic transformation with the onset of squamous cell carcinoma may occur ([Azevedo et al., 2015a](#)).

Differential Diagnosis

Paracoccidioidomycosis, leishmaniasis, sporotrichosis, tuberculosis and tertiary syphilis are the main differential diagnoses. CBM should also be differentiated from squamous cell carcinoma, lacaziosis, keratoacanthoma, psoriasis, sarcoidosis, leprosy and atypical mycobacterioses ([Queiroz-Telles et al., 2017a](#)).

Diagnosis

The definitive diagnosis consists in the observation of muriform cells under optical microscopy, by direct examination (10%–40% potassium hydroxide) of the lesion scrape or stained histological sections. Within the lesion, in areas rich in black spots usually contain the muriform cells. CBM agents are not inhibited by cycloheximide or chloramphenicol, allowing the use of selective media to prevent rapid growth of contaminants in culture. Colonies appear after 7–15 days as small, fuzzy black dots, which turn into dark velvety colonies (**Fig. 2(A)**). The fungal micromorphology (**Fig. 2(B)**) has various aspects, and its analysis using the slide culture is crucial for the classification of the genus of the agent ([Ameen, 2009](#)).

For species identification, molecular characterization by sequencing of the internal transcribed space region (ITS) of ribosomal DNA (rDNA) is recommended. In addition, taxonomic studies may apply specific genes, such as those encoding the cell division partial cycle gene (*cdc42*), β -tubulin (*BT2*), translation elongation factor 1- α (*TEF-1 α*) and actin gene (*ACT1*), among others ([de Azevedo et al., 2015](#)).

Histopathological findings of hyperkeratosis, pseudoepitheliomatous hyperplasia of the epidermis, pyogranulomatous reactions and irregular acanthosis alternating with areas of atrophy are the rule. Nevertheless, it is the presence of the muriform

Fig. 2 *Fonsecaea pedrosoi*. Credits to Rowena Alves Coelho, MSc. (A) Dark velvety colony (Potato dextrose agar). (B) Micromorphology – dematiaceous septate hyphae with short-chain *Cladosporium*-type conidiation (400x; Potato dextrose agar 30°C; 7 days).

cells in the interstitium or within Langhans multinucleated giant cells that seals the diagnosis. These naturally melanized pathognomonic structures of CBM can be easily identified by routine hematoxylin-eosin (H&E) staining. Gomori-Grocott and Fontana-Masson stains may be helpful when the fungal load is low (Uribe *et al.*, 1989).

Treatment

CBM therapy is long lasting and associated with low cure rates and high relapse rates, particularly in chronic and extensive disease. *Fonsecaea pedrosoi* is less susceptible to antifungals when compared to *C. carrionii* or *P. verrucosa*. There is no standard treatment and the association of more than one drug, or the use of physical methods is needed in most cases. Itraconazole 200–400 mg/day and terbinafine 250–500 mg/day are the most used drugs. There are reports of the combination of terbinafine with itraconazole, flucytosine and amphotericin B, flucytosine and itraconazole, fluconazole and itraconazole, which can be used in patients with refractory disease. *In vitro* studies have shown lower values of minimal inhibitory concentration (MIC) with terbinafine and voriconazole, and synergistic interaction of amphotericin B and flucytosine in *F. monophora* isolates, which may point to the use of these combinations. Physical methods such as heat therapy (daily sessions of 2–24 h), cryosurgery (monthly sessions of 30 s to 4 min) or excisional surgery may be used associated with systemic antifungal therapy. Few cases treated with photodynamic therapy and laser therapy had good response (Ameen, 2009; Coelho *et al.*, 2018).

Lobomycosis

Lobomycosis primarily occurs in tropical climates of Latin America. The causative organism is *Lacazia loboi* (formerly *Loboa loboi*), a dimorphic fungus found in soil, vegetation, and water (Paniz-Mondolfi *et al.*, 2012).

Infection occurs through the traumatic implantation of the fungus into the skin, and the most common presentation in humans consists of slow-growing, keloid-like papules, nodules, or plaques (Fig. 3). Other clinical presentations are ulcerated, infiltrative, verrucous, gumma-like, multifocal, and disseminated lesions (Woods *et al.*, 2010).

Although lobomycosis is the accepted term, other used names are Jorge Lobo mycosis, Amazonian pseudolepromatous blastomycosis, miraip, or piraip (“burning” in the Tupi language), Caiabi leprosy, and lacaziosis.

Etiology and Transmission

Lacazia loboi is a dimorphic fungus that may exist in a saprophytic phase in soil, vegetation, and water (Paniz-Mondolfi *et al.*, 2012).

Traumatic inoculation into the dermis is the most likely mode for the development of lobomycosis in humans (Borelli, 1962). Also, patients have reported the development of symptoms following snakebites, insect bites, or stingray stings (Campo-Aasen, 1958). The incubation period is estimated to be one to two years (Opromolla and Nogueira, 2000). Lobomycosis does not appear to spread through human to human transmission.

Epidemiology

The overall prevalence of lobomycosis is low. Tropical regions of South and Central America within areas of dense forests with high annual rainfall (>20 cm per year) and warm, humid environments (average temperature >24°C) are the sites of most significant predilection for the disease (Borelli, 1969).

Lobomycosis is more frequent in men than in women, and most commonly between 40 and 70 years old. In endemic areas, lobomycosis most often occurs as an occupational disease and occasionally as a recreational disease in individuals exposed to harsh outdoor environments, such as forest workers, farmers, hunters, and fishers (Woods *et al.*, 2010).

Fig. 3 Lobomycosis – keloid-like nodules on the skin overlying the mandible of a 54-year-old man. Credits to Fábio Francesconi, MD PhD.

Pathophysiology

After inoculation into the dermis, *L. loboi* replicates slowly within macrophages (Pecher *et al.*, 1979). Preserved cellular immunity is probably necessary to hinder the persistence and progression of the disease. Cytokines with suppressive effects on cellular immunity, notably transforming growth factor-beta 1 (TGF-beta 1) and interleukin-10 (IL-10), may play critical roles in the pathogenesis of lobomycosis. Besides, there is an upregulation of regulatory T cell markers in lesions (Azevedo *et al.*, 2015b). Regulatory T cells might inhibit Th-dependent, protective responses to intracellular fungi. The possibility that impaired cellular immunity increases susceptibility to lobomycosis is also suggested by studies that utilized skin tests to assess immunologic function (Pecher and Fuchs, 1988).

Clinical Features

The initial lesion of lobomycosis is a superficial or deep-seated papule, which may appear months to years after inoculation and slowly expands contiguously, leading to the formation of single or multiple monomorphic or polymorphic plaques or nodules that often resemble scars or keloids (Fig. 3). The surface of the plaques and nodules is usually smooth, shiny, and intact, and the color usually ranges from skin-colored to red-brown or wine-red. Telangiectasias may be present (Francesconi *et al.*, 2014). Other characteristics may also be seen, including dyschromia, ulceration, and infiltrative, verrucous, or gumma-like lesions (Brito and Quaresma, 2007).

Affected sites usually correspond to exposed skin, like the pinna, upper limbs, and lower limbs. Although localized lesions are the rule, multifocal (multiple sites of involvement on a single limb) and disseminated presentations may also occur. Regional lymph node enlargement, which may represent a lymphatic spread of the fungus, is estimated to occur in 10%–25% of patients (Woods *et al.*, 2010). Skin involvement is usually asymptomatic. However, patients with extensive involvement may experience pruritus or dysesthesia.

Diagnosis

The diagnosis of lobomycosis is based on clinical presentation, by identification of a keloid-like lesion in a person living in an endemic region. Microscopic confirmation is usually recommended, performed by clarification with 10% KOH of a small biopsy sample of the lesion (Fig. 4). The fungus does not grow on culture media; thus, this is not a useful method.

The most significant histologic findings of lobomycosis are in the dermis. Although the epidermis is usually normal or atrophic, the transepidermal elimination of the fungus is occasional. The dermis exhibits a dense histiocytic dermal infiltrate with a thin zone of collagen and abundant fungal structures of *L. loboi*, and the fungal structures are round with birefringent membranes and thick walls containing melanin. The fungus reproduces with simple gemmulation without sporulation, resulting in blastoconidia with chain-like or rosary-bead-like configurations (Francesconi *et al.*, 2014).

Treatment

The extent of disease is the main factor in deciding the treatment choice. For patients with localized lobomycosis, wide surgical excision is the preferred treatment. Despite the intent of total removal, recurrences are frequent. Other techniques with reported

Fig. 4 *Lacazia loboi* – numerous round yeast-like structures with birefringent membranes, some in a chain-like configuration (direct examination with 10% KOH; 100x). The sample was obtained with a 1-mm punch. Credits to Fábio Francesconi, MD PhD.

effectiveness in individual patients include cryosurgery and electrocauterization. There is no reliable effective drug antifungal treatment, and treatment failure is common. Data are primarily limited to case reports. Drugs used are itraconazole, clofazimine, posaconazole, ketoconazole, amphotericin B, sulfa compounds, 5-fluorocytosine, and combination drug regimens. All have showed incomplete or unsatisfactory effect. An incidental finding of favorable responses of lobomycosis among ten patients treated for concomitant leprosy in a dermatology department in Brazil may aid in the search for effective treatments for lobomycosis (Brito and Quaresma, 2007).

If not treated, the disease is usually slowly progressive with a potentially extensive or disseminated skin disease that can cause local tissue destruction and physical disability. Spontaneous resolution is rare. A few case reports document the development of squamous cell carcinoma in sites of longstanding lobomycosis. Long-term follow-up is mandatory since there is a high relapse rate (Nogueira *et al.*, 2013).

Mycetoma

Mycetoma is a chronic subcutaneous disease caused by traumatic inoculation of filamentous fungi (eumycetoma) or aerobic filamentous bacteria (actinomycetoma), which form grains in the tissue (van de Sande, 2013). Usually, there is an indolent clinical evolution, difficulty for laboratory diagnosis and challenging treatment. This disease presents significant medical, occupational and socioeconomic impact, with reduction in the quality of life of affected individuals (Queiroz-Telles *et al.*, 2011; Welsh *et al.*, 2014). Its incidence and prevalence are unknown, since it is not a notifiable disease.

Epidemiology

Mycetoma is also known as ‘Madura foot’ due to the city of Madurai, in India, where some of the first cases were better described and documented (McGinnis, 1996). Actinomycetoma accounts for 60% of cases worldwide, while the rest is eumycetoma (Welsh *et al.*, 2007).

Most patients are 15–30 years-old, with a gender ratio of 3.7 male:1 female. This male predominance is commonly attributed to a greater risk of occupational exposure, but genetic or immunological factors cannot be ruled out. Mycetoma is seen in most communities in farmers, field laborers and in herdsmen who come in contact with the land, although in endemic areas people from other occupations are affected (Fahal *et al.*, 2018).

Mycetoma occurs worldwide and prevails in tropical and subtropical regions. Although its true incidence is not known, most of the cases occur between latitude 15°S and 30°N, the so-called “mycetoma belt”. The endemic countries include Sudan, Somalia, Senegal, India, Yemen, Mexico and Venezuela. In South America, cases have also been reported in Colombia, Brazil, and Argentina (Fahal, 2011; Lichon and Khachemoune, 2006; Zein *et al.*, 2012).

The main agents of eumycetoma are *Madurella mycetomatis*, *Trematosphaeria grisea* (former *Madurella grisea*), *Falciformispora senegalensis* (former *Leptosphaeria senegalensis*), *Acremonium* spp., *Scedosporium apiospermum* and *Curvularia* spp. The most frequent agents of actinomycetoma belong to the genera: *Nocardia*, *Actinomadura* and *Streptomyces* (van de Sande *et al.*, 2018; Zein *et al.*, 2012). In the Americas, *Nocardia brasiliensis* is the leading cause of actinomycetoma (do Valle *et al.*, 2006). Cases by *Nocardia* spp. are more frequent in humid regions, while eumycetoma and actinomycetoma by *Actinomadura* spp. and *Streptomyces* spp. predominate in drier areas (Bonifaz *et al.*, 2014).

Grain color and morphology help to infer the etiological agent. Black grains are caused by dematiaceous fungi, mainly of the genera *Madurella*, *Curvularia* and *Exophiala*. Red grain is characteristic of *Actinomyadura pelletieri*. White or yellowish-white grains may be caused by fungi (*S. apiospermum* and *Acremonium* spp.), or by filamentous bacteria (*Nocardia* spp. and *Actinomyadura madurae*) (Kloezen *et al.*, 2012; van de Sande, 2013).

Pathophysiology

The main route of infection is by direct traumatic inoculation of the microorganism into the tissue, from thorns, wood, splinters, stones and sharp materials. Once in tissues, adaptative mechanisms such as cell membrane alteration favor survival and progression of infection in the host organism. The grain compounds seem to be partially responsible for the pathogenesis and antimicrobial resistance of the agents. Melanin, found in black grains, also appears to play a protective role against the immune system and antifungal medications (Ibrahim *et al.*, 2013).

Pathogen- host- and environment-related factors play a role in the pathogenesis. The initial nonspecific inflammatory response and neutrophil chemotaxis later become more organized and cellular. T helper 2-like responses [interleukin – 10 and 4] have been found in primary lesions of eumycetoma and in draining lymph nodes (Zijlstra *et al.*, 2016). A polymorphism resulting in decreased human chitotriosidase activity was associated with increased likelihood of eumycetoma (Verwer *et al.*, 2015).

Clinical Features

Mycetoma involves the skin and subcutaneous tissue to form the classic triad of a hard-woody swelling, painless discharging sinuses (Fig. 5(A)) and presence of grains, which are colonies of bacteria or fungi and vary in color and size, depending upon the organism (Verma and Jha, 2019). The discharge may be serous, serosanguineous or purulent (Fahal, 2011). Other clinical presentations may occur, but are rare, and include swelling without sinuses, cystic type and verrucous plaque type (Bonifaz *et al.*, 2014). The clinical presentations of eumycetoma and actinomycetoma are almost identical, the first (Fig. 6) being more chronic and less inflammatory than the second. The feet are by far the most common sites of involvement, but the disease may present in other parts of the body. Left untreated, the disease spreads through the fascia, bone and muscle, which makes the disease more difficult to treat (McGinnis, 1996; Verma and Jha, 2019). Pain may be produced by the expansion and invasion of the mass, but it is more commonly due to secondary bacterial infection (Fahal, 2011). Mycetoma affecting the back may lead to vertebral compression, causing neurological manifestations. An enlarged regional lymph node is not uncommon, and this may be due to secondary bacterial infection, genuine mycetoma lymphatic spread or may be due to local immune responses to mycetoma. Constitutional symptoms are rare but may occur due to comorbidities. Mycetoma can produce many disabilities, distortion and deformity. It can be fatal especially in cases of cranial mycetoma (Fahal, 2011).

Fig. 7 Eumycetoma grain in Gomori-Grocott methenamine silver impregnation under optical microscopy. Credits to Janice Mery Chicarino de Oliveira Coelho, MD PhD. (A) Grain within the dermis. (B) Thick septate hyphae forming the grain.

Differential Diagnosis

It is important to differentiate mycetoma from botryomycosis, actinomycosis, osteomyelitis with cutaneous manifestations, nocardiosis, fusariosis, chromoblastomycosis and phaeohyphomycosis. Other diseases to consider are: hyalohyphomycosis, atypical mycobacterioses, Kaposi sarcoma, cutaneous tuberculosis, melanoma, foreign body granuloma, osteogenic sarcoma, diabetic foot, among others (Fahal, 2011).

Diagnosis

Clinical samples should be collected at the depth of the lesion (needle puncture or biopsy) for histopathology and direct examination and culture (mycological/bacteriological). Fresh grain analysis can be performed by optical microscopy in 10% KOH (van de Sande *et al.*, 2014).

Grain visualization in histopathology sections is fundamental and can be performed with H&E. However, periodic acid-Schiff staining and Gomori-Grocott methenamine silver impregnation show better results (Fig. 7(A)). Fungal grains are composed of 4–5 µm thick septate hyphae (Fig. 7(B)), while actinomycetoma grains generally consist of branched and thin filaments or bacillary forms that are only 1 µm thick. Actinomycetoma filaments are Gram-positive and eumycetoma hyphae are Gram-negative (Chufal *et al.*, 2012). The grains are surrounded by polymorphic inflammatory cells (neutrophils, lymphocytes, histiocytes, plasma cells, epithelioid cells and giant cells) that constitute granulomas, and eosinophilic material (Splendore-Hoeppli phenomenon) (do Valle *et al.*, 2006; Fahal, 2011).

Actinomycetoma agents grow on Lowenstein-Jensen medium and eumycetoma on Sabouraud-dextrose agar incubated at 30 and 37°C for about 6–8 weeks. After growth, the species can be identified by macroscopic characteristics of the colony, by micromorphology and by biochemical tests. Agents within the genus *Nocardia* are usually indistinguishable (van de Sande *et al.*, 2014).

Molecular tests, such as DNA sequencing and polymerase chain reaction (PCR) (Ahmed *et al.*, 2014), are often necessary for determining the species of the microorganism. However, they are still expensive or not available, especially in the areas of mycetoma occurrence.

To assess the extent of lesions, radiographs, ultrasounds and magnetic resonance imaging (MRI) are the most useful exams. Radiography is usually the most available and inexpensive method to verify the existence of destruction, periosteal reaction and bone cavitation (Fig. 5(B)) (Fahal, 2011). Ultrasonography is also a low-cost, fast and easy-to-obtain exam. It can be performed in both reference centers and point-of-care, but it has the disadvantage of being operator-dependent. When compared to conventional radiography, it is a more specific technique for diagnosis. MRI has higher sensitivity and specificity, but it is expensive. Typical structures with high-signal areas seen on MRI are believed to represent inflammatory granulomata, the low-intensity tissue surrounding these lesions would represent the fibrous matrix, and the small central hypointense foci within the granulomata, the fungal balls or grains. This signal is considered by some authors as pathognomonic of mycetoma and is called “dot-in-circle” (Fig. 5(C)) (Sen and Pillay, 2011; Estrada *et al.*, 2012).

Treatment

Actinomycetoma is treated with sulfamethoxazole and trimethoprim at a dose of 800/160 mg twice daily, either alone or in combination with intramuscular amikacin or gentamicin sulfate, 15 mg/kg/day, for three weeks (Welsh *et al.*, 1987). This association with aminoglycoside improves cure rates to 90%. The average treatment is five to ten cycles to achieve clinical cure. Rifampin (10 mg/kg/day) may be used, but in many countries, it may compromise the treatment of tuberculosis and leprosy (Praveen Kumar *et al.*, 2011). Minocycline, amoxicillin/clavulanic acid, moxifloxacin, imipenem and carbapenem are also options (Welsh *et al.*, 2014).

Eumycetoma is treated with azoles, in particular itraconazole at a dose of 200–400 mg/day (Fahal, 2011). Posaconazole and voriconazole are indicated in cases refractory or intolerant to other antifungals, but they are still very expensive. Terbinafine can be used at a dose of 250–1000 mg/day as monotherapy or in combination with itraconazole for 6–12 months (Estrada *et al.*, 2012). However, *in vitro* studies do not support this as a first-line option in eumycetoma (Welsh *et al.*, 2014).

Complete excision is indicated in cases of single lesion or anatomically feasible, alone or associated with pharmacological treatment. Whenever possible, the association of antimicrobials before and after the procedure is pertinent due to possible recurrence. Actinomycetoma responds better to drug therapy when compared to eumycetoma and therefore surgery is less indicated. Cure rates vary from 25.9% for eumycetoma through 90% for actinomycetoma (van de Sande *et al.*, 2014). Amputation is indicated in cases of infection with massive bone destruction and/or unresponsive to drug treatment, secondary bacterial infection unresponsive to drug treatment or serious adverse drug effects. It is important to emphasize the exception character for such conduct, left for extreme cases. Amputated patients should receive early rehabilitation and use of appropriate orthopedic prostheses, mitigating the social impact (Asly *et al.*, 2010; Sampaio *et al.*, 2015).

Criteria for cure include disappearance of the clinical lesion, absence of activity detected by imaging, bone remodeling, and absence of abscesses and grains. The recurrence rate is around 25%–50%. Therefore, follow-up should be prolonged over years, with no time determined by scientific studies (Fahal, 2011; Zein *et al.*, 2012).

Subcutaneous Phaeohyphomycosis

Phaeohyphomycosis is caused by dematiaceous, i.e., darkly pigmented, fungi (Ajello *et al.*, 1974). They are termed for their natural melanin pigment in the wall, an important virulence factor of fungi infectivity. Phaeohyphomycosis has a wide range of clinical presentations: superficial, subcutaneous and disseminated disease. In this topic we focus on subcutaneous presentation.

Epidemiology

The agents of phaeohyphomycosis are ubiquitous in nature, present in soil and vegetation, and distributed worldwide. The number of genera and species of fungi causing phaeohyphomycosis is quite large. *Alternaria* spp. and *Exophiala* spp. are the most common agents in cutaneous phaeohyphomycosis, while other as *Bipolaris* spp., *Cladophialophora* spp., *Curvularia* spp., and *Phialophora* spp. have also been described (Severo *et al.*, 2012). Individuals can acquire the infection in professional or leisure activities. These infections are uncommon and can occur in both immunocompetent and immunocompromised hosts. The most common risk factors for infection are corticosteroid use and solid organ transplantation, mainly the kidney (Revankar *et al.*, 2017). Recently, a case of subcutaneous phaeohyphomycosis with CARD9 mutation was described (Huang *et al.*, 2019).

Pathophysiology

Traumatic implantation is frequently related, and dissemination is rare, but it can occur in immunosuppressed patients. Lung and central nervous system are possible involved sites (Revankar *et al.*, 2017; Schieffelin *et al.*, 2014; Vasikasin *et al.*, 2019).

Clinical Features

The most common presentation of subcutaneous phaeohyphomycosis is an indolent nodule or cyst in exposed areas of the limbs. These lesions tend to be solitary and asymptomatic. Other cutaneous lesions are papules, plaques, pustules, or ulcers, one or multiple (Caviedes *et al.*, 2017; Shields *et al.*, 2019; Tirico *et al.*, 2016).

Differential Diagnosis

Differential diagnoses include sporotrichosis, chromoblastomycosis, cutaneous tuberculosis, American tegumentary leishmaniasis, cutaneous nocardiosis, foreign body granuloma and synovial cysts, among others.

Diagnosis

The diagnosis of cutaneous phaeohyphomycosis is based on fungal culture and histopathology of tissue specimens. The typical histologic appearance is suppurative granulomas, with histiocytes and varying number of giant cells. Brown hyphae are evident in H&E and Fontana-Masson stains (Schieffelin *et al.*, 2014). PCR using ITS 1 region and D1/D2 analyzes are becoming more available for identification of this diverse group of fungi from clinical specimens (Santos *et al.*, 2013).

Treatment

Surgical resection associated with antifungal drugs is essential to cure. Treatment is indicated until the lesions heal. Most of the dematiaceous fungi are susceptible to azoles, making itraconazole, voriconazole and posaconazole the main drugs employed. Prolonged courses are necessary for non-surgery patients. Mortality related to cutaneous infections is rare whereas among patients with disseminated disease it approaches 70% (Revankar *et al.*, 2017).

Entomophthoromycosis

Also called entomophthoromycosis or subcutaneous zygomycosis (former name), this group involves subcutaneous mycoses caused by fungi of the order Entomophthorales, subphylum Entomophthoromycota, which includes Basidiobolomycetes (*Basidiobolus ranarum*), Neozygitomycetes and Entomophthoramycetes (*Conidiobolus coronatus* and *Conidiobolus incongruus*) (Kwon-Chung, 2012).

Epidemiology

These fungi are part of the soil microbiota, and have been isolated from insects, decaying vegetables, intestines of some reptiles, amphibians, and domestic and wild mammals. Although their prevalence is highest in tropical and subtropical zones in Africa, Asia and Latin America, the burden of basidiobolomycosis (*Basidiobolus ranarum*) might be expanding, with cases reported in the United States, Australia, Iran and Saudi Arabia (Rodén *et al.*, 2005; Shaikh *et al.*, 2016).

Pathophysiology

These organisms are believed to exert low virulence in human hosts. It has been proposed that infected patients may acquire the organism during a state of transient immunosuppression or as the result of repeated exposure. *Basidiobolus ranarum* may enter human hosts via insect bites or via minor trauma and subsequent inoculation due to contact with soil and vegetation with the agent. *Conidiobolus* spp. may be acquired via the inhalation of spores or from minor trauma (Shaikh *et al.*, 2016).

Clinical Features

Entomophthoromycosis may be classified as mucocutaneous, subcutaneous and deep visceral disease. Conidiobolomycosis mainly affects the mucocutaneous facial structures (rhinoentomophthoromycosis). It progresses slowly, with edema, disfigurement and sequelae (Gugnani, 1992; Rodén *et al.*, 2005). Rhinoentomophthoromycosis may cause intracranial impairment, resulting in a rhino-orbitocerebral infection (Shaikh *et al.*, 2016). Basidiobolomycosis is more prevalent in men than in women, and it also affects children. It starts with erythematous nodular lesions on the trunk and limbs that may converge and become necrotic, affecting muscles, bones, regional lymph nodes, and adjacent organs. Involvement of the gastrointestinal system has been reported, mimicking inflammatory bowel disease, especially Crohn's disease, and malignancy (Gugnani, 1999). Although affecting primarily immunocompetent patients, immunocompromised ones may be involved, with greater severity.

Differential Diagnosis

The differential diagnosis includes chromoblastomycosis, sporotrichosis, paracoccidioidomycosis, blastomycosis, coccidioidomycosis, pythiosis, rhinosporidiosis, mucocutaneous tuberculosis, atypical mycobacterioses, nocardiosis, tularemia and cat-scratch disease. Among noninfectious processes, differentiation from squamous cell carcinoma and cutaneous T-cell lymphoma is important (Cameroon, 1990).

Diagnosis

The mycological direct examination and culture of lesion specimens, along with the histopathology seal the diagnosis. Hyphae are broad, distorted, with very few septations, and show right-angle branching. Histopathology shows a chronic granulomatous inflammatory infiltrate composed by macrophages, epithelioid and multinucleate giant cells, plasma cells, lymphocytes and eosinophils, typically with Splendore-Hoeppli phenomenon.

When cultured, *B. ranarum* initially displays a gray to beige colony that is glabrous or waxy and becomes radially furrowed and covered with aerial hyphae over time. It grows moderately rapid at 30°C and slower at 37°C. The microscopy reveals hyphae with occasional septa, sporangiophores with terminal sporangiospore, club-shaped spores with a knoblike tip and distinctive intercalary zygospores with a beaklike appendage (Ribes *et al.*, 2000).

Conidiobolus spp. grow rapidly within 3–5 days at 37°C on conventional media as glabrous, flat, beige to brown colonies and develop scattered white aerial hyphae. The hyphae of *Conidiobolus* spp. display occasional septa. The sporangiospores of *Conidiobolus* have a distinct papilla and sporangiola are also formed. The spores may display hair-like structures called villi (Ribes *et al.*, 2000).

Molecular identification can be performed from paraffin embedded tissues. Different methods with specific DNA probes and panfungal primers, as well as real time PCR, are used.

Computed tomography or MRI are important to define the extent of the lesions, plan possible surgeries and monitor therapeutic response. In suspected cases of gastrointestinal disease, colonoscopy is useful for observing the lesions and for obtaining biopsies (Shaikh *et al.*, 2016).

Treatment

No controlled trials exist, but itraconazole is the therapy of choice (Queiroz-Telles *et al.*, 2017b), although for conidiobolomycosis the response tends to be disappointing. Potassium iodide has been used as monotherapy or in combination with itraconazole (Kamalam and Thambiah, 1979). Reports of terbinafine as an associated option also exist (Yang *et al.*, 2010). Surgical resection has its role, especially in initial conidiobolomycosis and in basidiobolomycosis. Voriconazole might be preferable for gastrointestinal basidiobolomycosis (Albaradi *et al.*, 2014). For severe and disseminated disease, amphotericin B formulations are indicated. Nevertheless, the MIC often signal a frustrating response (Guarro *et al.*, 1999).

Prevention

Protective measures are needed, like proper footwear, gloves, body protection and tools when dealing with soil and plants. Such measures are useful not only for those at occupational risk, but also for those who, for leisure, are in contact with the environment (Queiroz-Telles *et al.*, 2017a). Proper and feasible local behavior changes might be helpful.

Superficial Infections of the Skin and Nails

Priscila M de Macedo and Dayvison FS Freitas, Evandro Chagas National Institute of Infectious Diseases, Oswaldo Cruz Foundation, Rio de Janeiro, Brazil

© 2021 Elsevier Inc. All rights reserved.

Introduction

Superficial and cutaneous mycoses are diseases caused by fungi of the skin microbiome and environmental fungi, occurring either in the soil or colonizing animals. Clinically, there is a superficial involvement of the skin, usually limited to the *stratum corneum* and the naked hair shaft. In cutaneous mycoses, the host immune response is typically triggered, leading to an inflammatory process, usually absent or mildly seen in superficial mycoses.

Superficial Mycoses

Pityriasis Versicolor

It is the most prevalent superficial mycosis, caused by yeasts belonging to the genus *Malassezia*. To date, 14 species of *Malassezia* have been identified. *Malassezia furfur* (former *Pityrosporum ovale*), *Malassezia globosa*, and *Malassezia sympodialis* are responsible for the largest number of cases of pityriasis versicolor (Karray and McKinney, 2019). Other species described are *Malassezia pachydermatis*, *Malassezia obtusa*, *Malassezia restricta*, *Malassezia slooffiae*, *Malassezia dermatis*, *Malassezia yamatoensis*, *Malassezia nana* and *Malassezia japonica*.

P. versicolor has universal distribution being most prevalent in the tropics, where it can affect up to 40% of the population (Schwartz, 2004). There is no gender or race pattern but young adults are usually more affected due to hormonal issues. *Malassezia* yeasts are part of the microbiome of human skin. Pathogenesis involves a genetic predisposition and an imbalance in the host-fungus interaction (Sparber and LeibundGut-Landmann, 2017). As *Malassezia* yeasts are generally lipophilic, the disease is usually related to activities that cause intense sweating and the use of oily cosmetics. Other risk factors are diabetes, Cushing's disease, prolonged corticosteroid therapy, oral contraceptive use and pregnancy. Prematurity, malnutrition, parenteral nutrition, central venous catheter and immunodeficiencies can lead to an invasive and severe presentation, not discussed here (Pedrosa et al., 2018).

Clinically, *p. versicolor* is characterized by multiple round, sometimes confluent, well demarcated hypochromic macules (hypochromic variety), occurring predominantly in seborrheic regions such as face, shoulders, upper trunk, and arms. A thin scaling indicates disease activity (Fig. 1). The "evoked-scale" sign (Zireli's sign) corresponds to the scaling observed when the skin is stretched (Hudson et al., 2018). Some fungal metabolites have been linked to the clinical presentation of *p. versicolor* such as melanin, azelaic acid, and other products of skin lipid peroxidation. The hypothesis that cutaneous hypopigmentation is related to a competitive inhibition of the tyrosinase activity caused by *Malassezia*-produced azelaic acid is reported to be probably not relevant as this dicarboxylic acid cannot be synthesized in biologically significant quantities on diseased skin (Gaitanis et al., 2012). Lesions may also present brownish (hyperchromic or hyperpigmented variety) to erythematous colors. In case of atypical presentation, the Wood lamp may help revealing yellowish, gold or silver fluorescence related to the fungal production of coproporphyrin (Veasey et al., 2017).

The diagnosis is based on clinical picture; however, the skin scraping direct mycological examination with 10% potassium hydroxide (KOH) may help in the most atypical cases. Short fragments of curved and thick-walled hyphae usually without branches are observed on the skin scales (Fig. 2). Spherical thick-walled blastoconidia, alone or in groups, next to the hyphae, are also seen, some of them with phialide budding, typical of the *Malassezia* genus. *Malassezia* spp. do not grow in traditional media used in medical mycology because they are lipophilic fungi, requiring specific media such as Dixon's agar or Dixon's agar plus glycerol (Bonifaz et al., 2010).

Treatment is usually topical and indicated for limited or acute cases with keratolytic agents such as 20%–40% sodium hyposulfite, 2.5% selenium sulfide, 2% zinc pyrithione and antifungal imidazole compounds such as 2% ketoconazole, for 30 days. Shampoo or spray should be preferred as they are not oily. To prevent relapses, it is important to treat the scalp and all affected area, even the healthy skin. Associated systemic treatment is indicated for extensive, relapsing or chronic cases with itraconazole 200 mg/day, 5–10 days or fluconazole 450 mg as a single dose (Bonifaz et al., 2010). Sun exposure post-treatment is important to induce skin repigmentation. Narrow-band UVB was reported to be an effective alternative tool for extensive and recurrent cases unresponsive to conventional treatments, probably due to its immunomodulatory and inhibitory effect on *Malassezia* growth (Balevi et al., 2018). Prevention includes control of risk factors.

Tinea Nigra

Tinea nigra is a chronic superficial mycosis caused by the geophilic halotolerant dematiaceous fungus *Hortaea werneckii*. It occurs in tropical and sub-tropical regions and often affects young people, mainly children, who get in contact with soil. The first clinical

Fig. 1 Pityriasis versicolor – Multiple small round hypochromic macules with thin scaling on the upper trunk of a young man.

Fig. 2 *Malassezia* sp. on direct mycological examination showing short fragments of curved and thick-walled hyphae along with spherical thick-walled grouped blastoconidia. Credits to Paulo Cezar Fialho Monteiro, MD (*in memoriam*).

report was provided by Alexandre Cerqueira in 1891, in Bahia (Brazil). In the literature, there are 155 reported cases of *tinea nigra* in Latin America between 1966 and 2017 (Giordano *et al.*, 2018).

Clinically, non-scaly smooth brown-black asymptomatic macules on the palms of hands and soles of feet are observed. Dermoscopy is a useful tool to differentiate *tinea nigra* from nevi, and especially melanoma (Maia Abinader *et al.*, 2016).

In direct mycological examination of the cutaneous scales, *H. werneckii* is seen as branched and septate hyphae (Fig. 3(A)). The apical part of the hyphae is hyaline, has parallel walls and regular septation. The older parts have a brownish color, irregular cell wall and typical irregularly distributed septa. On Agar Sabouraud, colony is slow growing, initially yeast-like and shiny black. Over time, it develops abundant aerial mycelia (Fig. 3(B)). Microscopically, we observe numerous groups of two-celled brown yeasts with prominent darkly pigmented septa that taper towards the extremities forming an annellide (Fig. 3(C)). Also, brown to dark septate hyphae are present with one to two-celled conidia.

Treatment is topical with keratolytic and antifungal agents such as imidazoles, ciclopirox, terbinafine and butenafine with a good clinical response. Spontaneous cure can rarely occur (Rossetto and Cruz, 2012).

White Piedra

Trichosporon spp. are part of the skin microbiome (oral mucosa and inguinal regions) and are widely distributed in the environment (Schwartz, 2004). They can eventually cause soft nodules, known as white *piedra*, and are also responsible for opportunistic infections in immunosuppressed patients, mainly those with hematologic neoplasia.

Fig. 3 *Hortaea werneckii* – Credits to Paulo Cezar Fialho Monteiro, MD (*in memoriam*). (A) Direct mycological examination showing branched and septate black hyphae ($10\times$). (B) Macroscopic aspect of the colony on Agar Sabouraud, showing black velvety aerial mycelia folded in the center and with radial grooves. (C) Microscopy of the colony showing two-celled brown yeasts with prominent darkly pigmented septa.

A recent systematic review reported 106 cases of white *piedra* in the Americas, being 73.58% in South America, where the most endemic countries are Brazil, Colombia, and Venezuela. Mexico and the US had most of the cases from North America (Ramírez-Soto *et al.*, 2019).

Pathogenesis of white *piedra* is unknown. Clinically, it presents with clear, soft and asymptomatic nodules in the naked hair shaft of the pubic hair, axillary hair, beards, mustaches, eyebrows, eyelashes and scalp hair (Fig. 4).

In direct mycological examination with 10% KOH, the nodule of white *piedra* consists in a web of septate branched hyaline hyphae (Fig. 5(A)). Hyphae can fragment into oval or rectangular arthroconidia (Fig. 5(B)). There are no fungi parasitizing the inner layers of the affected hair. Fast-growing colonies on Sabouraud Agar are light beige in color, creamy or glabrous and sometimes develop radial furrows on their surface (Fig. 5(C)). Microscopically, they are composed by septate and branched hyaline hyphae that fragment into arthroconidia. Blastconidia are also seen.

Fig. 4 White *piedra* – Trichoscopy showing clear and soft yellowish nodules on the hair shaft of the scalp. Credits to Mariana de Almeida Seigneur d’Albuquerque, MD.

Treatment includes clipping or shaving hair in the affected area but recurrent cases are frequent, especially in endemic regions, where topical antifungals are indicated. Antifungal treatment is based on 2% ketoconazole shampoo for 1–2 months but oral itraconazole as well as keratolytics such as 1% salicylic acid preparations can be necessary in some cases (Bonifaz *et al.*, 2019).

Black Piedra

It is a rare superficial mycosis affecting the naked hair shaft caused by the geophilic dematiaceous filamentous fungus named *Piedraia hortae* (da Fonseca and de Arêa Leão, 1928). It occurs in the soil and water of riverbanks of tropical forests such as Amazon rainforest.

The fungus is acquired by the contact with humid soil, causing asymptomatic black and hard nodules, strongly adhered to the hair shaft of primates and humans.

On direct mycological examination with 10% KOH, nodules are composed by coiled dark hyphae (Fig. 6(A)). Large nodules constitute an ascostroma with some oval spaces between these hyphae containing ascus, each one with eight ascospores. On Sabouraud Agar media, slow-growing black glabrous colonies are observed, usually raised in the center and flat in the periphery (Fig. 6(B)). Microscopically, a web of septate, branched brown hyphae, sometimes with irregular cells and chlamydoconidia are seen.

Shaving or cutting the hair is the best treatment for black *piedra* as the nodules are strongly adhered (Schwartz, 2004). Additionally, topical antifungals and oral terbinafine can be used (Drake *et al.*, 1996). Due to cultural issues, treatment is not indicated for Brazilian Indians, as the nodules are considered beauty ornaments by some groups.

Cutaneous Mycoses

Dermatophytosis

These are cutaneous fungal infections of the hair, skin and nails, caused by specific filamentous fungi named dermatophytes. Historically, three anamorphic genera of dermatophytes were described: *Trichophyton*, *Microsporum* and *Epidermophyton*, while the known teleomorphs were distributed in the genera *Arthroderma* and *Nannizzia* (Lacaz *et al.*, 2002). However, the advent of polyphasic taxonomy, using methodologies of phylogeny and molecular biology, allowed the description of nine holomorphic genera: *Trichophyton*, *Epidermophyton*, *Nannizzia*, *Paraphyton*, *Lophophyton*, *Microsporum*, *Arthroderma*, *Ctenomyces* and *Guaromyces*, the first seven species being capable to cause infection in humans and/or other animals (de Hoog *et al.*, 2017a).

Dermatophytes are keratinophilic fungi, able to invade and degrade keratinized tissues, causing a variable inflammatory response. Anthropophilic dermatophyte species are more adapted to human tissues and usually trigger a milder inflammation when compared with zoophilic and geophilic species (de Hoog *et al.*, 2017b).

Dermatophytoses are common cutaneous infections, universally distributed, affecting individuals of all ages and both sexes leading to serious chronic morbidity. Changes in frequency and epidemiologic features of the disease have been increasing due to population mobility, changes in human lifestyle, and advents of antifungal drugs (Zhan and Liu, 2017). Transmission occurs

through human contact with infected individuals, animals, soil, and fomites. Epidemiology and clinical presentation varies according to the affected body site and the species of dermatophyte involved.

Dermatophytosis of the body (*tinea corporis*) affects the glabrous skin and is commonly known as ringworm. The most common agents are anthropophilic fungi, being *Trichophyton rubrum* the most common, followed by *Epidermophyton floccosum* and *Trichophyton mentagrophytes*. Clinically, the lesions present as annular plaques with central clearing, leading scale, and a ring-shape appearance (**Fig. 7**). They occur mainly on the trunk, limbs, and may be single or multiple, of varying sizes, and may coalesce (Kovitwanichkanont and Chong, 2019).

Dermatophytosis of the face and the beard (*tinea faciei*, *tinea barbae*) are less common clinical forms. Zoophilic species are mostly implicated such as *T. mentagrophytes* but anthropophilic dermatophytes can also be involved. Usually, there is an inflammatory pustular eruption with crusts resembling bacterial folliculitis, kerion presentation can also occur (Moriarty *et al.*, 2012).

Dermatophytosis of the scalp (*tinea capitis*) is almost exclusively a disease of childhood. It occurs in poor socioeconomic conditions and involves mainly the anthropophilic species *Trichophyton tonsurans* and the zoophilic *Microsporum canis*. The former usually presents with multiple scaly alopecic patches and poor or absent inflammatory signs (**Fig. 8**). The latter usually occurs as a large single alopecic patch and can be associated with a more intense inflammatory reaction. Diffuse scaling, black dots and diffuse pustular lesions can also be present (Moriarty *et al.*, 2012). Kerion Celsi is a clinical variant characterized by an exacerbated inflammatory response, usually misdiagnosed as bacterial infection. Late diagnosis of Kerion Celsi can lead to permanent scarring alopecia.

Fig. 7 *Tinea corporis*: single scaly ring-shaped patch on the left arm of a patient. Credits to Antonio Carlos Francesconi do Valle, MD PhD.

Fig. 8 Multiple round scaly alopecic patches without inflammatory signs.

Dermatophytosis of the hands (*tinea manuum*) affects the palmar surface and is usually unilateral. When it presents bilaterally, it must be distinguished from contact eczema and psoriasis for correct treatment. *Tinea manuum* is quite rare. On the contrary, dermatophytosis of the feet (*tinea pedis*) is very common. The main species involved in *tinea pedis* are *T. rubrum*, *T. mentagrophytes*, and *E. floccosum*. They may affect the plantar and interdigital areas causing erythema, and thin or laminar scaling. There are three

Fig. 9 Chronic squamous *tinea pedis* showing erythema and laminar scaling.

Fig. 10 *Tinea unguium* showing severe subungual keratosis.

main clinical variants: the interdigital form, the vesicobullous form and the chronic squamous form (Kovitwanichkanont and Chong, 2019). The interdigital form is the most common and presents with maceration or scales between toes, intense itching and eventually erythema and painful fissures. The chronic squamous form (moccasin-type) is clinically characterized by plantar erythema with scaling involving the lateral (Fig. 9) and plantar surfaces of the foot, and usually occurs due to anthropophilic fungi, mainly *T. rubrum*. The vesicobullous is an inflammatory, less common form, usually related to zoophilic and geophilic species.

Nail dermatophytosis (*tinea unguium*) is the most common nail infectious disorder and may have several clinical presentations according to the type of fungal invasion of the nail plate. Five major presentations are described: distal and lateral subungual, proximal subungual, white superficial, endonyx, and total dystrophic onychomycosis. The Distal and Lateral Subungual Onychomycosis (DLSO) is usually associated with *tinea pedis* because fungi reach the nail through the hyponychium invading the undersurface of the nail plate and spreading proximally. It usually affects one or both great toenails and it is usually caused by *T. rubrum*. The White Superficial Onychomycosis is usually caused by *T. mentagrophytes*, which invades the dorsal nail plate forming white opaque lesions, easily scraped away. The Proximal Subungual Onychomycosis (PSO) typically occurs in the ventral nail plate, producing a proximal leukonychia and it is rarely related to dermatophytes, being more observed in immunocompromised patients or related to non-dermatophyte infection. Endonyx Onychomycosis is very rare, caused by *T. soudanense* or *T. violaceum*, and is characterized by massive nail plate invasion without nail bed involvement. Total Dystrophic Onychomycosis occurs after long-term DLSO or PSO presenting severe subungual keratosis (Fig. 10), thickening, and dystrophy of the total nail unit plate (Piraccini and Alessandrini, 2015).

Dermatophytosis of the inguinal region (*tinea cruris*) is more frequent between adult men and presents as annular lesions with erythematous-scaly border on the groin. The main fungal agents involved are the same agents of *tinea corporis*.

Some special clinical presentations of dermatophytosis must be highlighted due to their specific characteristics. Majocchi granuloma is a deeper dermatophyte infection with dermic and follicular involvement and greater inflammatory reaction. *Tinea incognita* corresponds to a dermatophytosis lesion modified after topical or oral corticosteroids use, reducing inflammatory signs, making diagnosis difficult. *Tinea imbricata* is caused by *Trichophyton concentricum* (named after the concentric aspect of the skin lesions), occurring in the southwest Polynesia, Melanesia, Southeast Asia, India, and Central America (James et al., 2006). *Tinea corporis gladiatorum* can present in athletes (classically wrestlers) with extensive direct skin-to-skin contact (Yee and Al Aboud, 2019). In immunocompromised and susceptible patients, dermatophytosis may be a deep, extensive, severe and invasive disease (Nazarian et al., 2019).

A dermatophytid is a secondary, distant, hypersensitivity reaction that can occur as immunological response to a dermatophyte infection. The essential criteria for diagnosis are: (1) a proven focus of dermatophyte infection confirmed by fungal isolation in

Fig. 11 Direct mycological examination of the hair showing hyphae and arthroconidia distributed around and inside the tonsured hair shaft.

Table 1 Macroscopic and microscopic characteristics of most clinically important dermatophytes

Dermatophyte	Macromorphology	Micromorphology
<i>T. rubrum</i>	White colony with downy to velvety texture, and red reverse pigment	Delicate pyriform to claviform microconidia and cigar-shaped macroconidia (Fig. 12(A))
<i>T. mentagrophytes</i>	White to beige colony with powdery surface, brown reverse pigment	Clustered round microconidia, spiral hyphae, and claviform macroconidia (Fig. 12(B))
<i>T. tonsurans</i>	Beige colony with velvety to powdery texture, radial grooves, and reddish-brown reverse pigment	Long claviform to broad pyriform microconidia, cigar-shaped macroconidia, and clamidoconidia (Fig. 12(C))
<i>E. floccosum</i>	Beige velvety colony raised and folded in the center, yellowish-brown reverse pigment	Thin-walled macroconidia growing directly from the hyphae and numerous clamidoconidia (Fig. 12(D))
<i>M. canis</i>	White colony with fuzzy texture, bright golden yellow reverse pigment	Spindle-shaped, thick-walled macroconidia with more than 6 cells, and few pyriform to claviform microconidia (Fig. 12(E))
<i>Nannizzia gypsea</i>	Beige colony with granular texture, brown reverse pigment	Ellipsoidal, thin-walled, four to six-celled macroconidia, and numerous claviform microconidia (Fig. 12(F))

culture; (2) absence of dermatophyte isolation from the dermatophytid lesion, and (3) clearing of dermatophytid lesion after dermatophyte has been eradicated ([Al Aboud et al., 2003](#)).

Diagnosis of dermatophytoses involves the direct microscopic analyses of the skin and nail scales, where any dermatophyte presents as septate, branched hyaline hyphae that can disarticulate, resulting in arthroconidia. In hair, dermatophytes also appear as hyphae or arthroconidia chains being classified in three types of parasitism: (1) *ectothrix*, when hyphae and arthroconidia are distributed around and inside the tonsured hair shaft (**Fig. 11**); (2) *endothrix*, when hyphae and arthroconidia are distributed inside the tonsured hair shaft; and (3) *favic*, when hyphae and arthroconidia are distributed inside the hair shaft, without tonsure. Dermatophytes grow well in Sabouraud and Mycosel Agar after incubation at 25°C for 10 days on average. All dermatophytes are resistant to cycloheximide present in Mycosel Agar, which helps in their isolation in this media. The species are routinely identified by macroscopic (texture and pigment of the colonies) and microscopic (morphology and abundance of macroconidia and microconidia) analyses of fungi isolated in these media. Identification can also be provided by Matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF) ([L'Ollivier and Ranque, 2017](#)). **Table 1** summarizes macroscopic and microscopic (**Fig. 12**) characteristics of most clinically important dermatophytes.

Treatment of dermatophytoses usually requires topical antifungals although oral drugs (itraconazole, terbinafine) should be prescribed in case of extensive lesions, failed topical treatment, immunocompromised host, *tinea capitis*, and frequently for *tinea unguium* ([Kovitwanichkanont and Chong, 2019](#)). The time of treatment depends on the site of infection. Palm-plantar, hair and nail infections require longer time treatment. For prevention purposes, do not share objects of personal use, wear shoes in public collective environments, wash and dry feet and intertriginous areas well, avoid close contact with animals, fomites, and environmental sources as soil. In case of zoophilic transmission, it is important to take the domestic animal to veterinary evaluation and treatment, when indicated. When the agent involved is anthropophilic, it is recommended to examine all domiciliary contacts. Once treatment is started, the patient can return to his/her labor activities.

Candidiasis

Yeasts of the genus *Candida* are part of the oral, intestinal, vaginal and skin human microbiome although they can cause diseases when there is a host immune imbalance, favoring opportunistic invasion of the fungal agent. We herein briefly discuss some aspects of cutaneous candidiasis, as there will be a specific chapter for *Candida* infections.

The disease can occur in any gender or age group, prevailing in individuals with risk factors such as diabetes, antibiotic treatment, oral contraceptives use, pregnancy, as well as local conditions like heat, humidity and friction that lead to skin barrier impairment (Taudorf *et al.*, 2019). Some special clinical presentations must be highlighted due to their specific characteristics.

Candidiasis in the diaper area usually occurs in newborns between the third and fourth months, but it may also be present in adult patients requiring continuous use of diapers. Clinically, it presents shiny erythematous macules in the inguinal and diaper contact areas. Typical satellite papule-pustules are observed in the border of the lesion. The most important risk factors are the prolonged contact with urine and feces, or allergies to a diaper component.

Paronychia and onychomycosis due to *Candida* spp. usually affect the hand nails and cuticles. The main risk factor is the frequent contact with water, detergents and other chemical products. The inflammatory process of the nail fold is called paronychia and is acutely characterized by erythema, edema and pain. Chronic inflammation due to persistent exposure to risk factors may lead to a secondary involvement of the nail matrix, which may cause nail dystrophy, often misdiagnosed as onychomycosis. Onychomycosis is clinically characterized by detachment and thickening of the nail plate unit and may also lead to nail dystrophy.

Diagnosis involves clinical aspects and is reinforced by the presence of risk factors. Laboratory diagnosis involves direct examination with 10% KOH, where delicate septate hyaline hyphae, pseudohyphae and blastoconidia are observed (Fig. 13(A)). All *Candida* species grow on Sabouraud Agar, and some species are inhibited on Mycosel Agar. In general, the growth of white to cream yeast colonies (Fig. 13(B)) occurs in 3–5 days and the identification of the species can be done through morphological (clamidoconidia and germ tube production), biochemical (sugar assimilation and fermentation), MALDI-TOF and molecular tests (ITS region sequencing) (Aydin *et al.*, 2019).

Fig. 13 *Candida* sp. – Credits to Paulo Cezar Fialho Monteiro, MD (*in memoriam*). (A) Microscopy showing septate hyaline hyphae and pseudohyphae. (B) Macroscopy of the isolate showing a beige, white to creamy yeast colony.

Treatment of cutaneous candidiasis requires the use of azoles, which may be used topically (clotrimazole, nystatin and miconazole) or orally (fluconazole, itraconazole) depending on the extent of the lesion and the immune status of the host. Combination of antifungals with topical corticosteroids may be necessary if the inflammatory process is intense unless a concomitant underlying skin disease is present (Taudorf *et al.*, 2019). Control and, if possible, elimination of associated risk factors is important for the treatment and prevention of relapses.

Dermatomycoses

These are cutaneous mycoses caused by non-dermatophyte filamentous fungi (*Fusarium* spp., *Aspergillus* spp., *Penicillium* spp., *Acremonium* spp., *Scopulariopsis* spp., *Neoscytalidium* spp. etc.), which occur naturally in the environment or as plant pathogens. In humans, they behave as opportunistic agents (except *Neoscytalidium*), causing skin and nail disease (Cursi *et al.*, 2011).

They predominate in elderly patients, mostly affecting the palm-plantar regions, the toenails (Gupta *et al.*, 2016), and are clinically indistinguishable from dermatophytosis. They rarely affect the glabrous skin and the hair.

Diagnosis is based on the following criteria: (1) presence of dermatophytosis-like clinical lesion (especially in the plantar region and toenails); (2) direct microscopic examination with 10% KOH presenting hyphae similar to dermatophytes; (3) isolation of non-dermatophyte filamentous fungi from the lesion at least three different times to rule out the possibility of contamination (except *Neoscytalidium*); (4) fail to isolate dermatophytes; (5) growth absence of other contaminating fungi; (6) thermotolerance by growing agent at 37°C.

Treatment is challenging due to the host characteristics and to poor antifungal susceptibility profile, with high relapse rate and high tendency to chronicity (Gupta *et al.*, 2019). Some options are nail abrasion, nail laser therapy, ciclopirox or amorolfine nail lacquer, and oral terbinafine or itraconazole, with variable responses.

Introduction

Most fungal urinary tract infections are caused by *Candida* species. Infrequently urinary tract infections can also be caused by other pathogenic fungi including *Aspergillus*, *Cryptococcus*, *Histoplasmosis*, *Blastomyces* species and other rare fungal species. Candiduria is a common clinical finding that does not necessarily imply disease. *Candida albicans* are part of the human mycobiome and readily colonizes the skin, as well as mucosal surfaces of gastrointestinal and genital tracts (Bradford and Ravel, 2017; Neville *et al.*, 2015). Increasing numbers of patients with candiduria can be expected as the number of immunocompromised patients is steadily increasing with more aggressive chemotherapy in cancer patients and rising usage of therapeutics that alter the immune response either to prevent graft rejection during organ transplantation or to treat other autoimmune diseases (Kauffman *et al.*, 2000; Safdar *et al.*, 2005; Tsiodras *et al.*, 2008). Distinguishing when candiduria reflects a state of disease resulting in damage to the host is important because *Candida* can be recovered in up to 90% of hospitalized patients with indwelling urinary catheters (Fisher *et al.*, 2011a; Datta *et al.*, 2018; Padawer *et al.*, 2015; Yashavanth *et al.*, 2013) from urine specimens.

Definition and Diagnosis of Urinary Tract Diseases Caused by Fungi

Most clinical studies on funguria focus on candiduria, which is diagnosed by culture of urine. Yeast cells can also be seen on microscopic analysis of the urine and are reported as yeast cells per ml urine after growth. The threshold for the reported colony forming units (CFU) in candiduria varies between 10^3 – 10^5 yeast cells per ml urine (Kauffman, 2005; Achkar and Fries, 2010). It has been reported that standard urine culture methods on blood agar and Mac-Conkey plates, do not support the growth of all *Candida* species (Chaturvedi *et al.*, 2017). In addition, fungal UTIs can be a result of hematogenous spread from disseminated fungal infections especially in immunocompromised hosts (Kauffman, 2005). Diagnosis of genitourinary infections secondary to *Aspergillus*, *Cryptococcus*, *Histoplasma* or *Blastomyces* species has also been made by analysis of tissue stained with special fungal stains derived from biopsy specimens of a fungal ball, prostate abscess or transplant kidney (Guarner and Brandt, 2011). Furthermore, over the years several fungal antigen tests (summarized in Table 1) have been developed to detect diverse fungal antigens in the urine. However, these tests do not specifically signify genitourinary infection but rather detect shed cell wall derived antigens that stem from systemic infection and were filtered through the glomerular membrane.

Epidemiology of Candiduria

Reported incidence and prevalence of candiduria depend on the setting and the populations studied. Different urine culture methods can also affect candiduria prevalence and outcomes. The standard urine culture methods using Mac-Conkey and blood agar may not exhibit the same sensitivity to recover all *Candida* species and thus could result in underestimating the incidence of candiduria (Achkar and Fries, 2010). Contamination during collection is also common and complicates the matter further. Candiduria is rarely found in healthy individuals but is very common in hospitalized patients (Kauffman *et al.*, 2000; Alvarez-Lerma *et al.*, 2003). Multiple studies indicate that 10%–40% of nosocomial UTIs are caused by *Candida* species (Lundstrom and Sobel, 2001; Richards *et al.*, 2000; Shay and Miller, 2004; Toya *et al.*, 2007).

In the hospital setting, candiduria is regularly diagnosed in intensive care units (ICUs) as well as oncology and bone marrow transplant units (Kauffman, 2005; Richards *et al.*, 2000). Among the intensive care units, higher incidences are reported in burn units when compared to medical and surgical ICUs (Bougnoux *et al.*, 2008).

Common predisposing factors for candiduria in hospitalized patients include indwelling urinary tract catheterization, urinary tract anatomical abnormalities, prior surgical procedures, recent antimicrobial administration, prolonged hospital stay, older ages, female gender, diabetes mellitus, total parenteral nutrition (TPN) use, and immunosuppressive therapy (Kauffman *et al.*, 2000; Richards *et al.*, 2000; Kauffman, 2005; Bougnoux *et al.*, 2008; Lundstrom and Sobel, 2001; Harris *et al.*, 1999; Yang *et al.*, 2013; Febré *et al.*, 1999; Hamory and Wenzel, 1978; Paul *et al.*, 2007; Simpson *et al.*, 2004). Several studies demonstrate increased mortality in patients with candiduria (Kauffman *et al.*, 2000; Alvarez-Lerma *et al.*, 2003; Paul *et al.*, 2007). Factors associated with death in candiduric patients are the use of urinary diversion devices, prior antibiotic use (≥ 2 classes), ICU admission, and renal failure (Paul *et al.*, 2007). However, many of these factors may reflect the severity of underlying illness, rather than direct pathogenic effects of *Candida*. Compared to hospital-acquired candiduria, patients with

community-acquired candiduria tend to be younger and include a higher percentage of pregnant women. Similar to nosocomial candiduria, *C. albicans* is the most prevalent species in community-acquired candiduria, followed by *C. glabrata* and *C. tropicalis* respectively (Colodner *et al.*, 2008).

The percentages of concomitant candidemia in patients with candiduria ranges from 1% to 10% (Kauffman *et al.*, 2000; Bougnoux *et al.*, 2008; Paul *et al.*, 2007; Ang *et al.*, 1993; Storfer *et al.*, 1994). However, blood cultures are not consistently performed on candiduric patients and therefore the incidence of candidemia might be underestimated. Urinary tract obstruction is found to be a major risk factor for candidemia in patients with candiduria (Ang *et al.*, 1993).

Candiduria and candidemia are commonly diagnosed in neonatal and pediatric ICUs especially in premature newborns (Shay and Miller, 2004; Jarvis *et al.*, 1991; Triolo *et al.*, 2002). It is noteworthy that concomitant candidemia in neonates diagnosed with candida UTIs ranges between 33% and 52%, and is more common than in older children and adults (Phillips and Karlowicz, 1997; Bryant *et al.*, 1999). As a result, fungal balls in the collecting system are common findings in candida UTIs of critically ill neonates (Visser *et al.*, 1998). Although *C. albicans* is the also most common pathogen in candiduria in pediatric patients, *C. parapsilosis* is an emerging etiology of candiduria among neonates (Robinson *et al.*, 2009).

Microbiology

The distribution of candida species in urine is widely variable in different geographic regions. In most studies, *Candida albicans* continues to be the most common species isolated causing 50%–70% of the infections (Kauffman *et al.*, 2000; Alvarez-Lerma *et al.*, 2003; Simpson *et al.*, 2004; Gajdacs *et al.*, 2019). In more recent years, studies have reported candiduria can also be caused by non-*albicans* *Candida* species (Paul *et al.*, 2004; Ozhak-Baysan *et al.*, 2012). *C. glabrata* and *C. tropicalis* are the predominant non-*albicans* *Candida* species reported (Paul *et al.*, 2007; Ang *et al.*, 1993; Gajdacs *et al.*, 2019; Ozhak-Baysan *et al.*, 2012). Specifically, prior Fluconazole use is associated with an increased risk of *C. glabrata* isolation from the urine (Harris *et al.*, 1999). In immunocompromised patient populations non-*albicans* strains are becoming the dominant pathogens. For example, *C. glabrata* is a more commonly isolated fungal species (3% versus 35%) in renal transplant patients with candiduria than *C. albicans* (Safdar *et al.*, 2005). Mixed *Candida* species, mostly *C. glabrata* and *C. albicans* were co-isolated in 5%–10% of patients with hospital-acquired candiduria (Kauffman *et al.*, 2000; Bryant *et al.*, 1999). Molecular typing of sequential *Candida* isolates from patients with candiduria showed that recurrent infections occur due to the same strains (Jain *et al.*, 2007). The most recently, emerging multidrug-resistant species *C. auris* has also been reported as a cause of chronic candiduria with recurrent candidemia (Biagi *et al.*, 2019). Antifungal resistance profile of *Candida* isolates in urine depends on the infecting strains. Non-*albicans* strains are more commonly resistant to fluconazole (Toner *et al.*, 2016). Reported fluconazole resistance of *C. albicans* is between 1%–4% in contrast to 15%–25% for *C. glabrata* (Achkar and Fries, 2010).

Pathogenesis

Our understanding of pathogenesis of Candidiasis including UTIs has been informed by data from experimental rodent and rabbit models. Candiduria in these animal models is induced by intravenous infection of yeast which does not adequately mimic the ascending route in human infection (Kauffman, 2005). In rodent infection models, once candida invades from the renal artery into the kidney cortex; microabscesses form throughout parenchyma, followed by penetration of yeasts into glomeruli, renal tubules before they are shed into the urine (Kauffman, 2005). *Candida* species express several virulence factors to accomplish the commensal colonization and invade the tissue during infection, including adhesion, biofilm production, hyphal formation, phenotypic switching, and production of hydrolytic enzymes.

Normal urine flow is an important protective factor against microbial colonization or infection of the urinary tract. Adherence of *Candida* species to the host mucosal cells or the surfaces of indwelling urinary catheters is an essential virulent attribute to overcome the flow condition. It is the first step of colonization or infection. Adhesin facilitates adhesion of yeast cells to host tissue and formation of biofilms. In *C. albicans*, the agglutinin-like sequence (Als) proteins and the hypha associated GPI-linked proteins

(Hwp1) are the major adhesins (Hoyer *et al.*, 2008; Mayer *et al.*, 2013). Tamm-Horsfall glycoprotein, urine protein produced exclusively by kidneys, is found to prevent *C. albicans* colonization of bladder epithelium by specifically blocking Als3 protein (Coady *et al.*, 2018). Analogous, Epithelial adhesion proteins (Epa) and adhesin-like cell wall proteins (Awp) are principal adhesins in *C. glabrata* (Timmermans *et al.*, 2018) which exhibit a similar function as the Als proteins in *Candida albicans*.

Candida biofilms can form on urinary catheters. They are composed of mixed yeast and filamentous forms embedded in the extracellular matrix attached to the mucosal or artificial surfaces such as urinary catheters. They promote fungal growth and protect *Candida* species against host immune defenses (Wall *et al.*, 2019). Importantly, the organisms within the biofilms develop increased resistant levels to antifungal therapy especially azoles and polyenes (Hawser and Douglas, 1994; Pierce *et al.*, 2013). The *Candida* biofilms are intrinsically resistant to azole antifungal agents including fluconazole (Pierce *et al.*, 2013). Therefore, antifungal therapy is not likely to eradicate candiduria if the indwelling urinary catheters are not removed. Echinocandins are found to have excellent activity against *C. albicans* biofilms (Kuhn *et al.*, 2002). However, due to their poor kidney penetration and excretion, their use for treatment of fungal UTIs are limited (Groll and Walsh, 2000). In patients with chronic indwelling urinary catheters, candida biofilms on the catheters are likely the sources of candiduria rather than an infection of other components of the urinary tract (Fisher *et al.*, 2011a).

C. albicans can reversibly convert from budding yeasts to pseudohyphal and hyphal forms under different conditions. This morphological transition plays an important role in invasive candida infection and biofilm development. The yeast form is generally associated with dissemination whereas the filamentous or hyphal form facilitates the adhesion and invasion of host mucosal surfaces (Whiteway and Bachewich, 2007). During candida biofilm maturation, the yeast cells convert to hyphal or pseudohyphal cells forming a complicated network inside the biofilm (Wall *et al.*, 2019). In urinary tracts, certain conditions such as low pH or proteinuria can affect the morphological transition (Fisher *et al.*, 2011a).

Phenotypical switching is important for host colonization and contributes to virulence. In a rodent model, the *C. albicans* WO-1 strain can switch reversibly from white to opaque colony-forming phenotypes. The opaque-phase cells have greater cutaneous colonization capacity than the opaque-phase counterpart (Kvaal *et al.*, 1999). *C. tropicalis* can switch between five distinct phenotypes. Switching to crepe and rough phenotypes is associated with higher biofilm formation. Besides, certain switch phenotypes of *C. tropicalis* exhibit changes in susceptibility to itraconazole (Moralez *et al.*, 2014).

The extracellular hydrolytic enzymes are important in *Candida* virulence (Calderone and Fonzi, 2001). These enzymes can facilitate adherence, invasion of mucosal surface and blood vessels, and evasion of host immune defenses. Secreted aspartyl proteinases (SAPs) and phospholipases are key hydrolytic enzymes. SAPs hydrolyze structural proteins such as collagens, keratin as well as antibodies, complements, and cytokines. At least 10 SAP genes are identified in *C. albicans*. Different groups of SAPs are secreted at different stages of infection, such as colonization or symptomatic disease (Achkar and Fries, 2010). Phospholipases break down glycerophospholipids on cell membranes and promote tissue adherence, colonization and invasion (Ghannoum, 2000). *C. albicans* produce all phospholipases A-D. Phospholipase B is directly associated with pathogenicity (Ghannoum, 2000).

Candida species require multiple virulence factors discussed above to cause infection of the urinary tract. Different virulence factors may be predominant at different steps of UTI pathogenesis. In humans, *Candida* cells can reach the urinary tract either by hematogenous spread or by ascending from the vagina or perineum. Successful colonization of the urethra is the first step required for ascending infection. Interestingly, co-infection with enteric bacteria such as *Escherichia coli* and *Klebsiella pneumoniae* is found to increase susceptibility of the urinary tract to *C. albicans* infection in an animal model (Fisher *et al.*, 2011a). However, a recent in vitro study demonstrates that *E. coli* significantly suppresses *Candida* biofilm growth in a Foley catheter infection model (Samaranayake *et al.*, 2014).

Sodium-glucose cotransporter-2 (SGLT2) inhibitors (canagliflozin, dapagliflozin, and empagliflozin), which are a new class of antidiabetic agents, reduce blood glucose through increased glucosuria. Safety studies of these SGLT2 inhibitors have revealed slightly increased incidence of symptomatic UTI (Vasilakou *et al.*, 2013; Usiskin *et al.*, 2014). A tendency toward increased prevalence of candiduria in patients treated with SGLT2 inhibitors has been suggested (Nicolle *et al.*, 2012). A murine model of candida UTI demonstrated dapagliflozin-induced glucosuria significantly increased candida CFU in the kidney as well as UTI (Suzuki *et al.*, 2014). This clinical data indicates treatment with the SGLT2 inhibitors could be a risk factor for candiduria in diabetic patients.

Clinical Presentation and Diagnosis

Candiduria can be categorized into an asymptomatic and symptomatic infection. The majority of patients with candiduria have an asymptomatic infection (Kauffman *et al.*, 2000), a benign condition that reflects colonization without disease. In one large prospective multicenter study, only 4% of patients with candiduria have clinical UTIs (Kauffman *et al.*, 2000). *Candida* UTIs can involve any part of the genitourinary tract and thus present as cystitis, epididymo-orchitis, prostatitis, pyelonephritis or renal parenchymal abscess. In some cases, the latter can also present in an orthotopic transplant kidney. Diagnosis of candida UTIs can be challenging as standardized methods to differentiate colonization from true infection due to *Candida* are lacking (Kauffman, 2005; Lundstrom and Sobel, 2001). The first step in evaluating candiduria is to rule out contamination and colonization. Contamination can be excluded by obtaining a new urine sample either by mid-stream urine or a catheterized urine sample to

confirm candiduria (Kauffman *et al.*, 2011). In the case of a true UTI, it is important to determine what part of the urinary tract is affected (upper or lower).

Symptomatic candiduria can result in cystitis and/or pyelonephritis similar to bacterial UTIs. Their symptoms can be indistinguishable. The majority of patients with candiduria do not have associated candidemia. Candiduric patients with cystitis may present with dysuria, urinary urgency, frequency or suprapubic tenderness and occasional fever. In pyelonephritis, the primary clinical manifestation includes fever, chills, and flank or costovertebral angle tenderness. However, patients with indwelling urinary catheters may not have urinary symptoms and only complain of suprapubic or flank pain (Tambyah and Maki, 2000). Candiduria in the presence of urinary tract obstruction can result in candidemia (Ang *et al.*, 1993; Gross *et al.*, 1998). In addition, candiduria in critically ill patients can be a potential indicator for invasive candidiasis or candidemia (Kauffman *et al.*, 2011). Therefore, blood cultures and skin and fundoscopic examination may be warranted in these patients especially if there is a concern that candidemia was present for a prolonged time.

Although a rare presentation, *Candida* prostatitis is usually secondary to systemic fungal infection and can result in candiduria (Haas *et al.*, 1998; Wise and Shteynshlyuger, 2006). Symptoms and clinical findings are similar to bacterial prostatitis. Patients can present with fever, irritating voiding symptoms or possibly urinary retention, lower abdominal or perineal pain, pressure at the symphysis pubis. Bladder outlet obstruction such as benign prostatic hypertrophy can lead to formation of a prostatic abscess (Lentino *et al.*, 1984). The digital rectal examination usually reveals focal tenderness and fluctuance of prostate glands (Collado *et al.*, 1999). *Candida* epididymo-orchitis can also lead to candiduria. These patients present with testicular tenderness and enlargement or scrotal masses (Kauffman *et al.*, 2011).

Currently, there are no reliable diagnostic tests that can accurately distinguish candiduria due to colonization from infection. Although urinalysis of patients with candida UTIs can exhibit pyuria and yeasts, these constitute non-specific findings as they can be found also in patients with asymptomatic candiduria or indwelling urinary catheters. Data from rabbit models, suggests that detection of *Candida* casts may be a diagnostic marker for candida pyelonephritis but it is not a very sensitive finding (Navarro *et al.*, 1994; Argyle *et al.*, 1984). In contrast to bacterial UTIs, quantification of yeasts in urine has limited value for the diagnosis of candida UTIs (Kauffman, 2005; Kauffman *et al.*, 2011; Sobel, 2002). Higher colony counts of yeasts do not always indicate candida UTIs and CFUs as low as 10,000 CFU/mL of *Candida* can be found in patients with UTI (Kauffman, 2005).

Imaging studies can be useful modalities for confirming candida UTIs as well as evaluating the anatomical level of infection and complications such as urinary obstruction, perinephric abscess or fungal balls. Ultrasonography is the preferred initial study especially in patients with impaired renal function as it does not require intravenous contrast (Kauffman *et al.*, 2011). It can demonstrate hypoechoic kidney lesions as well as hydronephrosis. A presence of gas in kidneys suggests emphysematous pyelonephritis [58], which requires immediate evaluation by surgery as these complicated infections are associated with high mortality. Ultrasonography is also a diagnostic study of choice for epididymo-orchitis. Computed tomography scan is superior to ultrasonography in delineating the extent of pyelonephritis and perinephric abscess (Kauffman *et al.*, 2011). Transrectal ultrasound is a reliable imaging study to confirm prostatic abscess (Hildebrand *et al.*, 1999). It usually shows ill-defined hypoechoic lesions within an enlarged prostate gland.

Recent studies indicate an elevation of inflammatory cytokine, IL-17, in the urine of candiduric patients compared to non-candiduric patients (Ahmadikia *et al.*, 2018; Helbig *et al.*, 2013). The immunological biomarker may be a useful tool in differentiating colonization from *Candida* UTIs requiring treatment. A large prospective study will be necessary to further elucidate the role of biomarkers.

Treatment

A presence of candida in urine requires careful clinical evaluation to determine if antifungal therapy is needed. Even though candiduria is confirmed, antifungal therapy may not be warranted. Asymptomatic candiduria generally represent colonization and rarely lead to invasive disease (Kauffman *et al.*, 2000). It can resolve spontaneously or with the removal of indwelling urinary catheters alone. Hence candiduria is commonly overtreated with antifungal therapy (Jacobs *et al.*, 2018). Unnecessary exposure to antifungals can increase the risk of emergence of antifungal resistance in colonizing *Candida* species. The largest randomized controlled trial of treatment of asymptomatic candiduria demonstrated that 47% of candiduria was eradicated by the sole removal of indwelling catheters (Sobel *et al.*, 2000; Pappas *et al.*, 2016). Most importantly, although candiduria is associated with increased mortality, its treatment did not improve morbidity and mortality outcomes (Simpson *et al.*, 2004; Safdar *et al.*, 2005; Jain *et al.*, 2007). Therefore, antifungal therapy is not recommended in asymptomatic patients except for those with high-risk of dissemination such as neutropenic patients and newborns with very low birth weight. In addition, patients undergoing urologic procedures are at increased risk of candidemia during instrumentation and antifungal treatment before and after the procedure is required (Pappas *et al.*, 2016). Once a decision is made to treat candiduria, unnecessary antibiotics should be discontinued as well as eliminating predisposing factors when feasible (Pappas *et al.*, 2016; Fisher *et al.*, 2011b).

Fluconazole is considered the drug of choice for candida UTIs for most *Candida* species except for *C. glabrata* and *C. krusei* because of concern for preexisting or inducible resistance (Brammer *et al.*, 1990). Oral Fluconazole has > 90% bioavailability and 80% is excreted in urine as an active drug (Fisher *et al.*, 2011b). A dose of 200–400 mg daily for 2 weeks is recommended (Brammer *et al.*, 1990; Fisher *et al.*, 2011b). Other azoles including itraconazole, voriconazole as well as posaconazole are

minimally excreted as active drugs into the urine (Pappas *et al.*, 2016; Johnson and Kauffman, 2003; Herbrecht, 2004). Therefore, their usefulness for fungal UTI treatment is very limited.

The echinocandins (caspofungin, micafungin, and anidulafungin) are also poorly excreted in urine and hence are of little value for the treatment of candida cystitis (Boucher *et al.*, 2004). Although very limited clinical data, series of case reports have shown both success and failure of caspofungin and micafungin for treatment of candiduria (Sobel *et al.*, 2007; Kane and Muzevich, 2016; Malani, 2010).

Flucytosine, at 25 mg/kg orally four times daily, is another alternative drug for candida UTIs (Brammer *et al.*, 1990; Pappas *et al.*, 2016). It requires a dose adjustment in patients with renal insufficiency. When used alone for an extended period, treatment-associated resistance emerges quickly. Furthermore, high cost, bone marrow suppression, hepatotoxicity, and severe gastrointestinal side effects due to flucytosine have limited its utility (Pappas *et al.*, 2016).

Although associated with significant renal toxicity, amphotericin B (AmB) (Tambyah and Maki) deoxycholate, 0.5–0.7 mg/kg daily, is efficacious and can be useful in selected patients such as those who are critically ill. It is recommended for fluconazole-resistant *C. glabrata* and *C. krusei* (Pappas *et al.*, 2016). A single intravenous AmB dose is found to be effective for Candida UTIs due to prolonged urinary excretion (Wise *et al.*, 1982). However, the lipid formulations of AmB do not achieve adequate levels in the kidneys or urine (Pappas *et al.*, 2016). Bladder irrigation with a suspension of AmB has been used but its therapeutic value is not clear (Drew *et al.*, 2005). High relapse rates have been reported (Fisher *et al.*, 2003).

For upper UTIs, imaging studies to exclude urinary obstruction, papillary necrosis or persistent fungal ball is recommended (Pappas *et al.*, 2016). Candida UTIs refractory to medical treatment as well as complicated emphysematous UTIs and perinephric abscess often need surgical drainage and/or nephrectomy (High and Quagliarello, 1992; Kamaliah *et al.*, 2005; Ronald and Ludwig, 2001).

Due to the rarity of candida prostatitis and epididymo-orchitis, their treatment recommendation is based on anecdotal reports and expert opinions. Fluconazole is the agent of choice for fluconazole-susceptible organisms. AmB is another antifungal agent commonly used. Combination with surgical drainage or debridement is often required, especially for prostate abscess (Wise and Shteynshlyuger, 2006; Bartkowski and Lanesky, 1988).

Other Fungal Infection of Genitourinary Tract

Genitourinary tract infections caused by other fungal organisms are infrequent. Most cases have been reported in severely immunocompromised hosts. *Trichosporon asahii* is an emerging fungus causing systemic infections as well as localized UTIs in hospitalized patients. It is frequently associated with indwelling medical devices including urinary catheters (Urs *et al.*, 2018; Walsh *et al.*, 2004). *Blastoschizomyces capitatus*, another non-Candida yeast, has been reported as a cause of nosocomial UTIs (Krcmery *et al.*, 1999).

Cryptococcuria has been documented in patients with AIDS as well as in patients with other causes of immunocompromised state. It can be an early marker of disseminated disease such as meningitis and indicates a poor prognosis (Butler *et al.*, 1964; Severo *et al.*, 2011). In males, the prostate gland can serve as a reservoir of *Cryptococcus neoformans* and become a source of cryptococcuria and relapsed infection (Larsen *et al.*, 1989). Cryptococcal prostatitis is usually asymptomatic. Cryptococcal pyelonephritis is another source of cryptococcuria especially in renal transplant patients (Hellman *et al.*, 1981).

Genitourinary tract infection is a rare manifestation of disseminated Coccidioidomycosis likely from hematogenous spread. The sites of infection involve kidneys, prostate glands, epididymis, and testes (Halsey *et al.*, 2005; Sohail *et al.*, 2005; Yurkanin *et al.*, 2006). Fifteen to 30% of patients with systemic blastomycosis have genitourinary tract involvement. It frequently affects the prostate gland, epididymis and testes (Eickenberg *et al.*, 1975; Inoshita *et al.*, 1983). Most patients with prostatic involvement eventually have cutaneous lesions of blastomycosis (Inoshita *et al.*, 1983).

Aspergillus infection of the urinary tract can manifest as a perinephric or parenchymal abscess or aspergilloma in the renal pelvis (Bibler and Gianis, 1987; Lisson *et al.*, 2002). The latter can cause ureteropelvic obstruction.

Oropharyngeal and Vulvovaginal Candidiasis

Margaret E McCort, Albert Einstein College of Medicine, Bronx, NY, United States

Introduction

Although not always severe, oral and vulvovaginal *Candida* spp. infections represent some of the most common human infections. Since the fungus was first described by Bernard von Langenbeck in 1839, our understanding of *Candida* spp. as both a human commensal organism and a pathogen has continued to expand (Gow and Yadav, 2017; Lionakis and Edwards, 2019). Since the 1970s, the incidence of *Candida* infections has particularly accelerated as a result of widespread antibiotic use (Lionakis and Edwards, 2019). In addition, advances in antiretroviral therapy, malignancy treatment, and solid organ transplant has led to an increasing population of immunocompromised patients, many of whom are at increased risk for oral candidiasis, the most common opportunistic yeast infection (Martins *et al.*, 2014).

Candida albicans, the most common cause of oral and vulvovaginal candidiasis, accounts for 50%–90% of human candidiasis (Martins *et al.*, 2014). The names *Candida* and *albicans* are both derived from Latin words for white, referring to the typical white plaques of pseudomembranous candidiasis (Gow and Yadav, 2017). The yeast is a small pathogen, at 4–6 µm in size, and ovoid in shape, with thin walls (Lionakis and Edwards, 2019; Stoopler and Sollecito, 2014). *Candida* is a commensal organism present on the skin and in the gastrointestinal and vaginal tracts of healthy people (Lionakis and Edwards, 2019; Stoopler and Sollecito, 2014). *Candida* spp. can exist in yeast and hyphal forms, and reproduce by budding (Lionakis and Edwards, 2019; Stoopler and Sollecito, 2014).

Candidiasis is often diagnosed clinically, but can also be identified by the visualization of hyphae and pseudohyphae with 10% potassium hydroxide (KOH) smears or culture on Sabouraud dextrose agar (Lionakis and Edwards, 2019). Treatment of oral and vaginal candidiasis is often accomplished through topical polyenes or azoles, or with short courses of systemic azole therapy (Pappas *et al.*, 2016; Lionakis and Edwards, 2019). However, the rising incidence of non-*albicans* *Candida* species in human infection has been associated with increasing antifungal resistance for mucosal candidiasis (Sobel, 2016; Lionakis and Edwards, 2019).

Epidemiology

As a normal commensal organism of humans, *Candida* is frequently found in hospital and home environments; it has also been found in soil, animals, and food products (Lionakis and Edwards, 2019). Most infections occur endogenously, though human to human transmission is possible, as in cases of maternal-fetal transmission or from female genital tract to male balanitis (Lionakis and Edwards, 2019).

It is estimated that at least 75% of women will have an episode of *Candida* vaginitis during their lifetime, and 50% will have at least one recurrence (Lionakis and Edwards, 2019). Vulvovaginal candidiasis is especially common among pregnant and diabetic women, and in women undergoing antibiotic treatment (Martins *et al.*, 2014). Some women develop recurrent vulvovaginal candidiasis (RVVC), a syndrome that has only recently been widely recognized. RVVC is defined as three to four symptomatic episodes of vulvovaginal candidiasis per year, with asymptomatic periods in between (Sobel, 2016). RVVC is most common among women between ages 25–34, and represents a significant economic burden and negative impact on quality of life (Denning *et al.*, 2018). Rates of RVVC are estimated between 5%–9% of the female population (Sobel, 2016; Martins *et al.*, 2014; Lionakis and Edwards, 2019; Matheson and Mazza, 2017).

Oral and esophageal candidiasis predominantly affect neonates and adults with immunocompromising conditions such as HIV or malignancy, or individuals on steroid therapy (Pappas *et al.*, 2016). However, *Candida* is present in the normal oral flora of 45%–65% of healthy infants and 30%–55% of healthy adults (Millsop and Fazel, 2016). Patients using steroid inhalers, dentures, or suffering from xerostomia are at particular risk for oral candidiasis (Pappas *et al.*, 2016; Stoopler and Sollecito, 2014; Vazquez and Sobel, 2002).

Chronic mucocutaneous candidiasis is a rare condition that may be related to primary genetic mutations such as CARD9 deficiency, or associated with broader syndromes such as autoimmune polyendocrinopathy syndrome type 1 (also known as APECED) or thymoma-associated chronic candidiasis (Pappas *et al.*, 2016; Kirkpatrick and Windhorst, 1979; Glocker *et al.*, 2009). IL-17 deficiency, which impairs the host's innate immune response to *Candida*, may be the result of a primary genetic mutation or acquired from targeted destruction by immunotherapy (Netea *et al.*, 2015).

Pathogenesis

Our understanding of the process by which *Candida* changes from commensal, normal flora to problematic, opportunistic pathogen is still evolving. A failure of some aspect of the host's natural defense (such as incomplete immune response or break in

the epithelial barrier) is likely necessary to allow virulence factors of the fungus (including adhesion to epithelia, secretion of hydrolytic enzymes, and phenotypic switching) to prevail (Jayatilake, 2011).

A normal host mucosal immune response to candidiasis involves Th17 helper T cell activation, leading to production of cytokines (including IL-17 and IFN γ) that stimulate neutrophils and macrophages to kill the fungus (Netea *et al.*, 2015). Mucosal epithelial cells and platelets are also part of this complex immune response that involves adaptive, innate, and local host immune defenses (Netea *et al.*, 2015).

Interestingly, oral candidiasis is typically associated with immunocompromising conditions (such as HIV or malignancy) which do not predispose individuals to vulvovaginal candidiasis (which often occurs in healthy women) (Denning *et al.*, 2018). Additionally, some genetic mutations associated with mucosal candidiasis are not associated with invasive candidiasis, emphasizing the role of local immune response in the pathogenesis of these infections (Netea *et al.*, 2015).

Clinical Manifestations

Oral Candidiasis

Oral candidiasis most commonly presents with white lesions covering the dorsal tongue and buccal mucosa, as well as occasionally the soft or hard palates (Millsop and Fazel, 2016; Lionakis and Edwards, 2019). This classic presentation, called pseudomembranous candidiasis, manifests with confluent plaque-like lesions that can be easily scraped off to reveal irritated mucosa (Millsop and Fazel, 2016). Patients are sometimes without symptoms, or may complain of dysgeusia or burning sensation in the mouth. It is important to recognize atypical presentations of oral candidiasis as well, including “denture stomatitis”, which commonly presents with edematous erythematous gums, and “hyperplastic candidiasis”, which must be distinguished from leukoplakia on the buccal mucosa (Millsop and Fazel, 2016; Stoopler and Sollecito, 2014). *C. albicans* may also be implicated in angular cheilitis, presenting with painful fissures at the corners of the mouth, and central papillary atrophy of the tongue (Millsop and Fazel, 2016; Stoopler and Sollecito, 2014).

Esophageal Candidiasis

When *Candida* infects the epithelial lining of the esophagus, patients often complain of odynophagia or dysphagia. *Candida* esophagitis often occurs in conjunction with oral candidiasis, but esophagitis can occur without oral lesions (Lionakis and Edwards, 2019). Other less common symptoms of esophageal candidiasis may include chest pain, obstructive symptoms, nausea, epigastric pain, and vomiting (Telles *et al.*, 2017; Lionakis and Edwards, 2019; Vazquez and Sobel, 2002). If left untreated, as the yeast pseudomembrane extends and becomes invasive over time, the esophagus can become denervated, and patients may have less pain (Lionakis and Edwards, 2019). Esophageal candidiasis may appear similar to or occur simultaneously with viral (herpes simplex or cytomegalovirus) esophagitis, especially when there are both ulcers and pseudomembranes present (Lionakis and Edwards, 2019).

Vulvovaginal Candidiasis

Vulvovaginal candidiasis classically presents with symptoms of intense vaginal itching or discomfort associated with a thick, clumpy discharge and vulvar edema (Lionakis and Edwards, 2019; Sobel, 2007). Dyspareunia and dysuria may also be reported (Gonçalves *et al.*, 2016; Sobel, 2007). Differential diagnoses include bacterial vaginosis, trichomoniasis, and gonorrhea (Gonçalves *et al.*, 2016). As previously noted, recurrent vulvovaginal candidiasis involves several episodes of these symptoms associated with mycologic diagnosis within one year (Sobel, 2016).

Syndromes Involving Candidiasis

Chronic mucocutaneous candidiasis (CMC) is a disease characterized by recurrent oral and skin candidiasis that is commonly associated with immune dysfunction (Millsop and Fazel, 2016). CMC may occur independently in relation to an isolated genetic mutation, or may be part of a larger syndrome such as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), which may present in conjunction with hypoparathyroidism or adrenal insufficiency (Ferre *et al.*, 2016; Glocker *et al.*, 2009; Netea *et al.*, 2015).

Diagnosis

The gold standard for diagnosing all mucosal *Candida* infections involves microscopic identification of yeast forms from the site of suspected infection (Vazquez and Sobel, 2002; Telles *et al.*, 2017). Because *Candida albicans* is part of the normal flora of the gastrointestinal and female genital tract, it is imperative that symptoms or signs suggestive of infection be present in order to make the diagnosis.

Practically, candidiasis is often diagnosed presumptively in patients with risk factors for infection, classic symptoms, and typical signs on exam. Diagnosis is confirmed when these individuals respond quickly to antifungal therapy. However, in patients with atypical, recurrent, or refractory presentation, a suspected lesion can be swabbed or biopsied. Hyphae of *Candida* can be then be visualized under the microscope with samples that have undergone Gram staining, 10% KOH preparation, or periodic acid-Schiff staining (Telles *et al.*, 2017). Fungal culture on Sabouraud agar may be performed to determine antifungal susceptibilities in cases that recur or persist despite usual treatment. However, fungal culture for mucosal candidiasis is not routinely necessary and cannot distinguish between colonization and infection (Vazquez and Sobel, 2002).

For vaginal candidiasis, the vaginal pH is almost always normal (Sobel, 2016). Simple saline wet mount preparation of vaginal secretions under the microscope are about 40%–50% sensitive for the diagnosis of vulvovaginal candidiasis (Vazquez and Sobel, 2002); KOH microscopy examinations from vaginal samples are about 40%–70% sensitive (Sobel, 2016). Alternative diagnoses should be considered and fungal cultures obtained if the microscopic examination is negative (Sobel, 2016).

In esophageal candidiasis, endoscopic visualization with biopsy should be pursued if a patient presenting with classic symptoms does not respond to standard therapy (Lionakis and Edwards, 2019). Radiographic findings, such as filling defects or irregularities on barium contrast studies, may be suggestive of *Candida* esophageal infection, but are nonspecific (Vazquez and Sobel, 2002).

Diagnosis of chronic mucocutaneous candidiasis, endocrinopathies, or other primary immune deficiencies manifesting with recurrent oral, esophageal, or vaginal candidiasis requires a high degree of clinical suspicion and specific tests for genetic mutations (such as Th-17 deficiency) and immune function (Telles *et al.*, 2017; Ferre *et al.*, 2016).

Treatment

Because *Candida albicans* causes the majority of oral, esophageal, and vulvovaginal candidiasis, the treatment for different forms of mucosal candidiasis are often similar. Fortunately, *Candida albicans* tends to be fairly susceptible to many of the available antifungal agents, with only rare instances of antifungal resistance in heavily-antifungal-exposed patients.

Treatment of oral candidiasis consists of containing an overgrowth of yeast as well as removing the underlying risk factor, if possible. For mild oral candidiasis, topical antifungals such as clotrimazole troches or nystatin suspension for seven days is often adequate (Pappas *et al.*, 2016). Nystatin is a polyene antifungal medication available in many topical forms that inactivates yeast by binding an enzyme called ergosterol in the fungal cell membrane (Millsop and Fazel, 2016). For more severe oropharyngeal candidiasis, oral fluconazole tablets (200–400 mg daily) is recommended, and courses may be one to two weeks depending on clinical improvement (Pappas *et al.*, 2016). Azole medications disrupt fungal cell membranes by inhibiting ergosterol synthesis (Millsop and Fazel, 2016). For patients with oral candidiasis related to denture use (denture stomatitis), washing the dentures regularly in an antifungal solution may reduce recurrences (Pappas *et al.*, 2016). Individuals using steroid inhalers should be educated on rinsing out the mouth following inhaler use to reduce recurrence. Where possible, treatment of an underlying immune deficiency predisposing to oral candidiasis will also help resolve the infection and prevent recurrences, as in the case of starting antiretroviral therapy for HIV/AIDS (Millsop and Fazel, 2016; Pappas *et al.*, 2016). For patients with chronic recurrent oral candidiasis, prophylaxis with 150 mg fluconazole three times weekly has been suggested as a safe and effective regimen (Pappas *et al.*, 2016).

Topical agents are not effective for *Candida* esophagitis (Vazquez and Sobel, 2002). Rather, the first line treatment is oral fluconazole (at a higher dose such as 400 mg daily) for fourteen days (Pappas *et al.*, 2016). Intravenous fluconazole at the same dose may be used instead in patients without parenteral access (Vazquez and Sobel, 2002; Pappas *et al.*, 2016). Other oral triazole agents (posaconazole and itraconazole) are likely as effective as fluconazole in patients who have developed resistance to or intolerance of fluconazole (Vazquez and Sobel, 2002). Micafungin, an intravenous echinocandin antifungal, may be used in patients with esophageal candidiasis who cannot tolerate azoles, though the dose should be 150 mg daily (Pappas *et al.*, 2016). Intravenous liposomal amphotericin B has largely fallen out of favor for the treatment of mucosal candidiasis, but may be used for patients with azole-refractory esophagitis (Vazquez and Sobel, 2002). Treatment duration for any of these regimens may be extended to 21 days in patients with severe disease (Pappas *et al.*, 2016).

First line treatment of uncomplicated vulvovaginal candidiasis is topical antifungal agents (such as clotrimazole cream, miconazole suppository, or nystatin cream) or a single dose of 150 mg oral fluconazole tablet (Vazquez and Sobel, 2002; Pappas *et al.*, 2016). Topical agents are effective in about 80%–85% of uncomplicated cases (Gonçalves *et al.*, 2016). For severe acute vulvovaginal candidiasis, three doses of 150 mg fluconazole given every 72 h may be used (Pappas *et al.*, 2016). Although topical agents have fewer risk of systemic side effects, oral azole therapy is often preferred for convenience and ease of use (Vazquez and Sobel, 2002; Gonçalves *et al.*, 2016). Pregnant women should be treated with topical agents, as oral azoles are not recommended due to the risk of fetal toxicity (Pappas *et al.*, 2016). For recurrent vulvovaginal candidiasis, treatment begins with an induction course of one to two weeks of 150 mg oral fluconazole every 72 h followed by a maintenance treatment of fluconazole 150 mg weekly for six months (Pappas *et al.*, 2016; Sobel, 2016; Matheson and Mazza, 2017). For vulvovaginal candidiasis due to non-azole susceptible *Candida* such as *Candida glabrata*, vaginal boric acid or flucytosine may be attempted (Sobel, 2016).

It has been suggested that probiotics may have a beneficial effect in reducing oral candidiasis recurrence by lowering the quantity of *Candida* in the oral flora, but evidence for this remains limited (Mundula *et al.*, 2019). Similarly, probiotics have been suggested for recurrent vulvovaginal candidiasis on the basis of increasing the proportion of *Lactobacillus* present in the bacterial

microbiome, but there is not yet enough evidence to definitively recommend this (Xie *et al.*, 2017; Sobel, 2016). Novel antifungal therapies currently being studied for vulvovaginal candidiasis include TOL-463, a vaginal insert that targets the fungal biofilm, and VT-1161, an oral medication which inhibits the fungal lanosterol demethylase enzyme (Marrazzo *et al.*, 2019; Brand *et al.*, 2018).

Fungal Infections of Human Mammary Gland During Lactation

Breastfeeding

Breastfeeding is the optimal way of infant feeding. The World Health Organization recommends exclusive breastfeeding from birth to the age of six months. Then it recommends to continue breastfeeding, while expanding the baby's diet, at least until the age of two (World Health Organization, 2001). Numerous studies indicate the irreplaceable role of breastmilk in optimal growth and development of a child's body. The breastmilk is perfectly matched to the needs of a developing organism providing all the necessary nutrients. The milk composition varies with the age of the breastfed child (Andreas *et al.*, 2015). Breastmilk is considered a functional food due to the fact that in addition to nutrients, it also contains elements that support development and maturation. Particular importance is attributed to the influence of natural feeding on the proper development of the immune system (Silvers *et al.*, 2012). Bioactive components of human milk support the innate and acquired specific immunity of the body (Ballard, 2013). Feeding with human milk, due to its beneficial effect on immunity, reduces susceptibility to gastrointestinal and respiratory tract infections, urinary tract infections (Maldonado *et al.*, 2012) and in the case of illness it contributes to a milder disease course. Feeding children at early stage of development with breastmilk brings not only short-term benefits, such as: protection against infectious diarrhea, respiratory tract infections, otitis media, but it is also an investment for the future (Hoddinott *et al.*, 2008). A diet consisting of breastmilk contributes to reduced risk of civilization diseases development in later life, including type II diabetes mellitus, obesity, hypertension or hypercholesterolemia (Dieterich *et al.*, 2013; McCrory and Layte, 2012). Breastmilk is an extremely important source of biologically valuable ingredients, including probiotic microflora (Fernández *et al.*, 2013; Donnet-Hughes *et al.*, 2010). Human breastmilk is an abundant source of microorganisms belonging to the probiotic microflora (Latuga *et al.*, 2014). Colonization by microorganisms occurs during the child passage through the mother's birth canal, during skin to skin contact and with breastmilk consumption. Breastmilk is one of the main factors shaping the microbiological balance of the newborn's digestive tract (Martín *et al.*, 2003). Benefits of microbial homeostasis are both short and long-term. Composition of the microflora stabilizes between 2 and 7 years of age. Adequate supply of probiotic microorganisms supports the correct microbiological profile formation and ensures maximum benefits from the gastrointestinal tract microbiological homeostasis. Probiotic microorganisms affect the maturation and immune system development (Toscano *et al.*, 2017). Breastmilk contains not only probiotic microorganisms that affect the composition of the intestinal microflora, but also factors supporting its growth, such as oligosaccharides, considered to be prebiotics (Marcobal *et al.*, 2011). Breastfeeding has also a beneficial effect on the mother's health. Scientific research confirms that breastfeeding contributes to reduce the incidence of women with such diseases as breast cancer, hypertension, diabetes, hyperlipidaemia, and cardiovascular disease (Newcomb *et al.*, 1994; Dieterich *et al.*, 2013). Although breastfeeding is a natural activity for the human species, it often causes many difficulties, especially at the initial stage of lactation. During this period, the support of a young mother is particularly important (Govoni *et al.*, 2019). Both psychological and physiological factors can affect the breastfeeding failure. The discomfort experienced during breastfeeding can be caused by the anatomical conditions or infections (Amir, 2003). Pain felt during breastfeeding is a common cause of premature weaning (Schwartz *et al.*, 2002). One of the causes of breast inflammation is fungal infections. There are no definitive data on the incidence of fungal infections among breastfeeding women, however, the problem is significant due to the susceptibility of this population group to infections and the consequences it causes (including premature weaning and termination of lactation). Breastfeeding women are a group susceptible to bacterial and fungal infections due to the resulting environment, conducive to the growth and development of pathogenic microorganisms. Lack of medical intervention and the spread of the disease may be the reason for worsening of the disease state, feeling of discomfort and, as a consequence, premature resignation from breastfeeding, which is unfavorable from the point of view of both the child and the mother (Kent *et al.*, 2015). Early diagnosis helps to control the problem and return to the optimal way of feeding child in comfort.

Structure of the Mammary Gland

The mammary glands are made of glandular tissue – the breast body (corpus mammae) and adipose tissue – the fat body (corpus adiposum mammae). In addition, the structure of the gland also forms a network of blood and lymphatic vessels, as well as nerves (Jesinger, 2014). On the skin, in the middle or slightly below the center of the gland, there is a dark colored areola of the nipple (areola mammae) with centrally located nipple (papilla mammae). The papilla is equipped with muscle fibers, which at the base pass to the areola and radiate there. At the top of the nipple, there are the outlets of the milk ducts (ductus lactiferi), which form a branched network in the gland. Their role is to remove the produced milk. The papilla (areola mammae) is equipped with radially arranged smooth muscle fibers. On its surface, there are skin glands: sebaceous, sweat and Montgomery's apocrine glands (Montgomery glands). The breast glandular tissue is made of lobes (lobi glandulae mammariae) and smaller structures – lobules (lobuli glandulae mammariae). Their number varies individually. Ultrasound studies allowed for verification of previous knowledge about the internal structure of the mammary gland. Previously, it was thought that glandular tissue in the breast forms

from 15 to even 25 lobes. There are currently around 9 (Ramsay *et al.*, 2004; Kent *et al.*, 2005; Ramsay *et al.*, 2005). There is often an additional lobe of the mammary gland, located partly in the armpit, called Spence's tail. Alveoli (the smallest structures) are surrounded by myoepithelial cells, smooth muscle cells, the work of which depends on hormonal changes (Jesinger, 2014). The size of a woman's breast is mainly determined by the amount of fat, which does not affect the breast productivity. Fatty tissue in the breast, in the largest amount, is located under the gland and around it at the base. It is also found in smaller amounts between breast structures (Geddes, 2007). The gland is surrounded by a capsule of fibrous connective tissue that penetrates the gland's parenchyma forming its stroma in the form of Cooper ligaments (Cardoso *et al.*, 2015).

Pathogenesis of Fungal Breast Infections

Nipple and breast mycosis is an infection caused by fungal microorganisms *Candida albicans*. *Candida* spp. are commensal organisms. Their presence does not always mean infection (Amir *et al.*, 2013). *Candida albicans* is a physiological microflora of the gastrointestinal tract, genitourinary system, respiratory system and skin. In healthy people, it does not lead to infection. Under certain conditions, for example reduced immunity, disturbance of the natural balance in the species composition of the human microflora, excessive proliferation occurs, which results in the appearance of the disease state. In the non-lactation period, female breasts do not show high susceptibility to fungal infections (Tanguay *et al.*, 1994). *Candida albicans* prefers a moist environment. Dry, hairless and intact breast skin does not create favorable conditions for excessive fungi multiplication. The situation changes during lactation. Breastfeeding increases the likelihood of excessive moisture and skin damage, which are the gate to infection (Tanguay *et al.*, 1994). Increasing the humidity of the skin of the mammary gland may be favored by the incorrect use of lactation pads. Breastfeeding women often use them, especially in the first period of lactation. Their proper use consists in frequent replacement of inserts for new ones, which allows the breast environment to be kept clean. Replacing the pads too rarely results in an increase in the humidity around the nipple and promotes the microorganism's growth (Amir, 1991). A factor that significantly increases the risk of developing a fungal infection is the use of antibiotic therapy (Tanguay *et al.*, 1994). Antibiotics lead to the elimination of pathogenic microorganisms but at the same time adversely affects the general condition of human microflora, also destroying beneficial probiotic bacteria. The situation worsens if during and after antibiotic therapy no cover is used in the form of supply of probiotic bacteria. Disorders of the natural balance of microorganisms in the human body result in a number of adverse phenomena, including a decrease in immunity and thus an increase in sensitivity to opportunistic and pathogenic microorganisms. Under conditions of disturbed homeostasis, the commensal microorganisms can multiply and lead to disease symptoms (Sullivan *et al.*, 2001). Factors that increase the likelihood of a fungal infection are also all the other elements that reduce the immunity of the human body. A woman, who has recently given birth to a child and is struggling with many emerging problems, is exposed to a large dose of stress, which is destructive to the body's defenses. Chronic sleep deprivation, anxiety, and an unbalanced diet can significantly contribute to the failure of the immune system. Because the nursing mother and breast-feeding baby stay in close contact with each other, any infection can easily spread between them (Johnstone and Marciniak, 1990). Studies confirm the correlation between the incidence of maternal fungal inflammation and the incidence of oral fungal infections in a child. Thrush in a child, caused by the yeast *Candida albicans*, can become a cause of fungal infection of the mother's breast. On the other hand the mother can become the source of the child infection. By taking food from the breast, the child is exposed to the transmission of microorganisms along with milk or directly from the surface of the nipple. Thrush is manifested by white coatings occurring on the oral mucosa. The observed changes cause pain and thus impede sucking. Cutaneous candidiasis in the diaper area often coexists or is a consequence of a child's oral thrush (Harris, 1958). A serious problem during lactation are mechanical injuries to the nipple caused, among others, by incorrect attachment of the baby to the breast (Tanguay *et al.*, 1994). They arise most often at the beginning of breastfeeding. They can be the gate to infection for microorganisms. In addition, the strong discomfort they cause may discourage women and become a reason for giving up the breastfeeding. A factor that promotes fungal infections of the breast may also be inflammation of the breast caused by factors other than fungal microorganisms. A positive correlation between the occurrence of vaginal fungal infections and fungal breast infections is also observed (Hanna and Cruz, 2011). In case of difficulties with breastfeeding or need to have more time spent separately from a child, a lot of mothers are opting for an alternative form of feeding with breast milk using breast pump. Mothers express breast milk for a variety of reasons (Labiner-Wolfe *et al.*, 2008). The benefits of breastfeeding for both child and mother are still preserved, but this way of feeding presents many difficulties. It is a time-consuming process, which is particularly troublesome at the initial stage of lactation and the child's life, when feeding sessions are long and feeding intervals are relatively short. In this case, the woman must schedule regular breast milk removal between feedings. Unfortunately, it has been observed that breast pumps can become a serious source of microbial contamination, including fungi such as *Candida albicans* (Jiménez *et al.*, 2017). If it is necessary to use this type of equipment, it is important to maintain the highest hygiene standards. It is of key importance to maintain high hygiene in the process of expressing milk from the breast and keep the breast pump clean. It has been proved that symptoms appearing after a fungal infection of the mammary gland can also appear as a result of infections caused by other microorganisms such as staphylococci, streptococci (Amir *et al.*, 2011; Kvist *et al.*, 2008) and corynebacteria. It happens that such cases are mistakenly diagnosed as candidiasis of the mammary gland (Delgado *et al.*, 2008; Mediano *et al.*, 2017; Hale *et al.*, 2009; Thomassen *et al.*, 1998). Treatment of incorrectly diagnosed women reporting symptoms of breast pain leads to unnecessary pharmacological burden on the body. In addition, desired effects of treatment in the form of improvement in the patient's condition are not observed and the risk of infection becoming chronic.

Candida albicans

Candida albicans – a microorganism that is part of the human saprophytic microflora. Under normal conditions, it lives in the digestive tract, on the skin or in the external organs of the genitourinary system (Bernhard and Knoke, 1997). Under favorable conditions for *Candida* spp. and in the situation of reduced immunity of the human body, uncontrolled multiplication of these microorganisms may occur, resulting in an imbalance between the host organism and the fungus and the appearance of the disease process (Hube, 2004). It can cause surface fungal infections of the skin but also life-threatening systemic fungal infections. The virulence factors are complex and are being learned all the time. Among them, there are molecules that mediate adhesion to and invasion into host cells, the secretion of hydrolases, the yeast-to-hypha transition, contact sensing and thigmotropism, biofilm formation, phenotypic switching (Mayer et al., 2013; Calderone and Fonzi, 2001). *Candida albicans* is a polymorphic fungus that can appear as single cells or form hyphae that are more (Liu, 2002). This dimorphism depends on external factors such as environmental pH, presence of CO₂, serum, N-acetylglucosamine or availability of nutrients. *Candida albicans* can enter the host cells in two ways. One of them is induced endocytosis. Invasive binding ligands of the host (Als3, Ssa1) are of major importance in this process. The second way is active penetration, the molecular mechanisms of which are not yet fully understood. The hydrolases secreted by *Candida albicans* (proteases, phospholipases and lipases) participate in this process. *Candida albicans* has the ability to adapt to a wide environmental pH. In addition, it also has the ability to affect the pH value of the environment by its alkalization. This process promotes the formation of hyphae. The source of nutrients for *Candida albicans* can be glucose, proteins, amino acids or lipids. The use of specific ingredients depends on the environment in which it is located. The ability to adapt the fungus in terms of metabolism is extremely important. Changing environmental conditions determine the cycle of metabolic changes. *Candida albicans* is able to absorb nutrients in the form of glucose and metabolism by glycolysis. In the event of entry into the phagocytic cells of the host's immune system, the metabolic pathway is switched to gluconeogenesis and lipids and amino acids become the source of nutrients. A feature that helps colonize both abiotic and biotic surfaces is the ability to create a biofilm (Nobile et al., 2009; Xie et al., 2012). Biofilm is a structure formed by microorganisms that increases their resistance to external factors (Taff et al., 2012; Robbins et al., 2011). The extracellular matrix produced by microorganisms has a protective effect (Finkel and Mitchell, 2011; Uppuluri et al., 2010). In the case of fungal infections of the breast during lactation, it is important to remember about high hygiene of the breast pump components. On individual parts of this device, fungi can form coatings in the form of a biofilm being a source of pathogenic microorganisms release. *Candida albicans* is a cause of vulvovaginitis that affects most women during the life. Factors conducive to the occurrence of this disease are a state of reduced immunity, concomitant diabetes, use of antibiotics, oral contraception, pregnancy and hormone therapy (Mayer et al., 2013). *Candida albicans* is widely believed to be the cause of pain problems among breastfeeding women. However, results of the tests carried out up to date are not conclusive. Some researchers recognize the dominant role of *Candida albicans* in the pathogenesis of breast pain in breastfeeding women. Others are of the opinion that the problem is much more complex and indicate a number of factors underlying the ailments discussed (Kaski and Kvist, 2018). *Candida albicans* cannot always be cultured from samples taken from women reporting symptoms, on the other hand *Candida* spp. cannot be excluded.

Symptoms of Fungal Breast Infections

Fungal infection can lead to pain that gets worse during breastfeeding. Felt pain is a stinging pain that can radiate. It covers one or both breasts. It often gets worse after feeding a baby. Pain in fungal infections is a prolonged pain of varying severity. The use of lactation pads, breastfeeding or warm compresses does not bring a relief (Amir et al., 2013). Itching and redness of the nipple may appear, as well as damage to the skin surface in the form of cracks or flaking (Heinig et al., 1999). In addition, increased breast tenderness is observed, which hinders normal functioning. Discomfort is felt with the slightest nipple irritation. Fungal infection may be complicated by a bacterial infection. In these cases, the symptoms overlap. As a result of the disease process, milk production in the mammary gland may decrease. The cause of this condition is the infectious process itself but also the limitation of the baby's attachment to the breast caused by the mother's breast pain during breastfeeding. The mother's body perceives the reduced frequency of attaching a baby as a signal for reduced food demand, which results in reduced milk production (Kent, 2007). Symptoms associated with fungal infection are nonspecific and are difficult to correct diagnose. The causes of nipple pain during lactation are very diverse. Differential diagnosis is very important so that the applied treatment is effective. Pain that occurs exactly during breastfeeding may indicate mechanical injury to the nipple. When applying warm compress brings relief, the cause of breast pain may be vasoconstriction (Amir et al., 2013). Fungal infection of the mother's mammary gland can easily spread to the baby's body and occur in the form of oral thrush. In this case, the child experiences severe discomfort when taking food. White round deposits appear on the mucous membrane of the mouth. These layers are easy to separate from the mucosa surface. Scrapped reveal red, bleeding spots. A thick white coating on the surface of the tongue is also observed. The presence of these symptoms may indicate the ongoing disease process in the mother and the need for treatment. It can also be a reason for the development of fungal infection in the mother's breast (Tanguay et al., 1994).

Diagnosis of Breast Fungal Infections

Early recognition of disease symptoms enables quick and effective therapy. It allows to return to feeding child in comfort, which indirectly reduces the risk of preterm weaning. Both clinical history and visible symptoms are important in diagnostics. An external

evaluation of the appearance of the breast can help to recognize the ongoing disease process. This may be indicated by skin discoloration from red to purple, swelling or tightening of the breast skin (Francis-Morrill *et al.*, 2004). As a result of excessive tension on the skin of swollen breasts, radiating stretch marks may appear. A history of stabbing pain and increased nipple tendency dominate. If symptoms indicating a fungal infection occur in the mother or child, both the child and the mother should be diagnosed. Transmission of infectious agents between mother and child is very easy and treatment of only one from the tandem mother-child can lead to recurrence of pathological symptoms and lack of success in treatment. In the child's examination, white deposits can be observed on the surface of the oral mucosa and on the tongue. An additional symptom may be a red diaper rash (Seifi *et al.*, 2017). The pain felt by the child affected by thrush causes his reluctance to feed. During feeding, a characteristic flexing of the baby can be observed, which indicates the discomfort felt during sucking. Diagnosis of fungal infections is routinely based on the clinical picture and history. Many scientific studies indicate the ambiguous cause of pain reported by breastfeeding women (Kaski and Kvist, 2018). It is important to exclude technical difficulties during breastfeeding. Many problems in breastfeeding arise from the wrong technique of attaching the baby to the breast or abnormalities regarding the process of suckling. In addition, anatomical conditions of the child may affect the occurrence of pain during breastfeeding (Hogan *et al.*, 2005; Ghaheri *et al.*, 2017) and cause a misdiagnosis. Additional tests, such as milk microscopy and skin scraping do not give a precise answer regarding the sources of observed symptoms. This is due to the fact that *Candida albicans* constitute human commensal microflora. In addition, microbiological testing of milk not always proved the presence of *Candida albicans* in milk samples (Hale *et al.*, 2009). This makes these studies not in the widespread use, although they could limit the cases of unjustified use of antifungal drugs in the case of misdiagnosed breast candidiasis and precisely target the patient's treatment (Jiménez *et al.*, 2017). Pain that occurs at the beginning of lactation is often caused by physiological hypersensitivity of nipples. Sometimes, it occurs at the beginning of lactation. The pain occurs at the beginning of breastfeeding and after a while passes. In this case, the best solution is to wait out this period. It is not recommended to temper the nipples during pregnancy. Such behavior is sometimes propagated among women expecting a child, while the use of these techniques can lead to unnecessary injuries and is not medically justified. Raynaud's syndrome should be included in the differential diagnosis. Severe pain for breastfeeding women with Raynaud's syndrome is caused by the vasoconstriction of the nipple tip (Wu *et al.*, 2012). Often the trigger factor for vasoconstriction, and thus the occurrence of a pain reaction, is a sudden change in temperature. In the case of Raynaud's syndrome, the symptoms usually relate only to temporary changes in the color of the nipple and areola, as well as pain during breastfeeding. No skin changes in the form of injuries, dry or flaky skin surface are observed. Symptoms will also not appear in a breastfed child.

Treatment

Treatment of fungal infections of the mammary gland and thrush in a child using appropriate antifungal preparations is not complicated. Both mother and child should be treated because of the ease of transmitting the pathogen (Brent, 2001). Topical antifungal drugs are used in the therapy. Oral antifungal drugs may also be used (Riordan and Wambach, 2010). It should be remembered that oral medications may pass into breast milk. It is recommended to check active substances ability to pass into breastmilk. For example, therapy with fluconazole is possible (Bodley and Powers, 1997; Chetwynd *et al.*, 2002). The dose that a breastfed child takes is lower than that used in systemic treatment (Kaplan *et al.*, 2015). For this reason, the active substance fluconazole is considered to be a substance with very low risk for breastfeeding. When choosing the right treatment it should consider severity of symptoms and their duration. The duration of treatment usually lasts for a week after which the symptoms disappear. If symptoms of oral thrush occur in the child's mouth, antifungal drugs are applied after each feeding (Kent *et al.*, 2015). The use of these medicaments must be carried out very carefully, especially in case of children under six months of age. There is a risk of choking. The best form of applying medicaments on the surface of oral mucosa is lubrication by finger. In the treatment of a child whose mother has been diagnosed with breast mycosis, probiotic therapy may be used as a protection (Matsubara *et al.*, 2016) however, any supplements must be consulted with the pediatrician. Child may also need treatment for genital and anal fungal infections (Scheinfeld, 2005).

Prevention of Fungal Breast Infections

In the prevention of fungal infections, it is important to prevent situations that promote the multiplication of microorganisms. A high level of personal hygiene should be maintained and the nipples should be kept dry. Frequent replacement of breast pads or complete abandonment of their use is helpful. Attention should also be paid to the quality of underwear and clothing in contact with the breasts. Fabrics that facilitate air access to the skin's surface are preferred (Riordan and Wambach, 2010). It is also important to avoid mechanical injuries to the nipple during breastfeeding. Emphasis should be placed on a solid preparation of women expecting a baby for breastfeeding. Education is of great preventive importance (Miracle and Fredland, 2007). Correct attachment of baby to the breast will help to avoid dangerous cuts (Cox, 2007). In the case of problems with attaching a baby to the breast, it is worth use the help of certified lactation counsellors, who will help diagnose and solve the problem. They have experience in capturing abnormalities that are the cause of incorrect milk intake by the child, which may result in nipple injuries. There are many positions that mother and baby can take during breastfeeding. The appropriate settings are selected individually, depending on the problem that arises. It is also recommended to ventilate the breast for several minutes a day. Exposing breasts to fresh air helps maintain proper conditions and allows the skin to rest in some way (Riordan and Wambach, 2010). When using

baby teats or lactation pads, care should be taken to keep them clean and replace them regularly with new ones. These kind of accessories are personal items for the child. Regular washing and disinfecting helps maintain an appropriate level of microbiological purity and prevents from infections, including fungal infections (Sachdeva *et al.*, 2016). Also, the use of equipment that enables the milk collection, such as breast pumps, creates an additional potential source of contamination, including fungi (Jiménez *et al.*, 2017). The basis for maintaining safety in this case is also maintaining the highest hygiene of the process and the breast pump itself, which should be thoroughly washed and dried after each use. Prevention is of the highest importance. Mothers should take care of the immunological resistance, preventing from chronic exhaustion, stress and providing all necessary nutrients in the diet. Women after childbirth are exposed to a high dose of stress, including that connected with lactation problems. In this situation, it is important to ensure support for mothers with breastfeeding problems (Labarere *et al.*, 2005). Early reporting of observed changes and ailments is important to stop pathological state spreading. Any abnormalities found at an early stage of development are easier to solve and the mothers can come back to breastfeeding in comfort (Kent *et al.*, 2015). It has been shown that breast milk is also a source of fungi (Heisel *et al.*, 2019). Research results indicate the dominant share of fungi *Malassezia*, *Candida* and *Saccharomyces*. These fungi have been found in human milk samples of healthy women, which may indicate the involvement of fungi in shaping the correct newborn's microbiome (Boix-Amorós *et al.*, 2017). The mechanism of fungi entering the breast milk environment is not fully understood. The entero-mammary path is taken into account (Heisel *et al.*, 2019).

Conclusions

Fungal infections of the breast are a disease that may contribute to the resignation of mothers from breastfeeding. They are the reason for felt discomfort and pain. In addition, they can become a cause of a fungal infection in a breastfed child, which affects the sensation of pain when feeding and unwillingness to suck. Precise problem identification of the problem and accurate diagnosis is not easy, but the quick implementation of appropriate treatment and compliance with hygiene rules allows for recovery and breastfeeding in comfort.

Central Nervous System Fungal Infections

Over the last few decades, cases of life-threatening fungal infections of the central nervous system (CNS) have significantly increased. Specifically, immunocompromised populations, the number of which has expanded in recent years, suffer from high mortality rates due to these infections (Murthy and Sundaram, 2014). The expansion of the immunocompromised population is due to increase in advanced transplant procedures, the use of immunosuppressive therapies, and the pandemic spread of HIV (Raman Sharma, 2010). The increased prevalence of these infections challenges physicians and researchers across the globe to develop accurate and rapid diagnostics associated with effective management strategies (Panackal and Williamson, 2015; Raman Sharma, 2010). In fact, research on fungal brain infections has produced impressive publication records over the last 20 years (Fig. 1).

Pathogenic fungi comprise approximately 300 species among highly diverse fungi, of which an estimated 1.5 million species are found living as saprophytic organisms that colonize distinct environmental niches, including some in animals and human hosts. Among the species able to colonize and cause disease in mammalian hosts, only approximately 10%–15% are able to colonize the CNS, where they cause severe infection (Murthy and Sundaram, 2014; Goralska *et al.*, 2018).

Upon exposure to fungi, immunocompetent individuals are generally able to defend against and avoid infection, having effective clearance. However, an immunocompromised host who is not able to fight the infection develops disease that generally begins in the lungs and skin and can be disseminated elsewhere in the organism, including the CNS, through hematogenous spread (Murthy and Sundaram, 2014; Black and Baden, 2007; Rauchway *et al.*, 2010).

Brain colonization is not an easy task for fungal pathogens, since the CNS is surrounded by a relatively impermeable blood–brain barrier (BBB). This barrier makes the CNS an immunologically privileged site, where few immunological cells, mainly activated T-lymphocytes, are able to penetrate. However, in immunocompromised hosts, the BBB permeability is increased, which facilitates fungal penetration into the CNS (Raman Sharma, 2010).

Fig. 1 Genus-based distribution of documents resulting from research on fungal brain infections from 1998 to 2018. Google Scholar (<https://scholar.google.com.br>) searches combining each fungal genus with the term “brain” indicated *Candida*, *Aspergillus*, *Cryptococcus*, *Fusarium*, *Pneumocystis*, *Histoplasma*, *Rhizopus*, *Blastomyces*, *Mucor* and *Coccidioides* as the top 10 fungal genera producing research documents. In combination, these 10 genera produced more than 200,000 research documents.

Although the host's immunological status has an important role in brain colonization, fungi have also evolved strategies to modulate and evade the host immune system. **Fig. 2** presents an overview of the most common fungi that causes CNS infections, represented by yeasts (*Cryptococcus* spp. and *Candida* spp.), filamentous (*Aspergillus* spp.) and dimorphic (*Histoplasma capsulatum* and *Coccidioides* spp.) species, together with the number of cases of each type of mycosis that is diagnosed per year and the frequency with which these mycoses can disseminate to brain tissue to cause lethal CNS diseases.

Candida species are known for their capacity to cause an invasive disease that can affect the CNS. Invasive candidiasis presents with a high incidence rate of CNS involvement (Panackal and Williamson, 2015), and has a mortality of 10%–70%, which is increased to 90% for patients in which the CNS is involved (Goralska et al., 2018; McCarthy et al., 2017; Pana et al., 2017). The most common manifestation of *Candida* spp. CNS infection is meningitis, which mostly affects newborns and neurosurgical and immunocompromised patients (Panackal and Williamson, 2015; Murthy and Sundaram, 2014); however, it can occasionally affect healthy patients (Borha et al., 2009).

Aspergillosis can also affect the brain and is associated with mortality rates of more than 90% (Baddley et al., 2010; Deigendesch et al., 2017). In addition to its ability to cause meningitis, the most common CNS infection by *Aspergillus* affects intra-axial brain structures (Deigendesch et al., 2017). Immunocompromised patients are the individuals most commonly affected by invasive aspergillosis, with bone marrow transplantation, hematological diseases, AIDS, pulmonary diseases, chronic granulomatous disease, and solid organ transplantation among the most common risk factors (Ruhnke et al., 2007; Singh and Paterson, 2005; Potluri et al., 2014).

Coccidioidomycosis is an endemic mycosis caused by the dimorphic fungi *Coccidioides immitis* and *C. posadasii* that, in addition to being commonly asymptomatic, can evolve to a disease that is disseminated with CNS involvement, leading to meningitis, which is the most serious form of the disease (Galgiani et al., 2005; Johnson et al., 2018). Although able to affect immunocompetent individuals, *Coccidioides* meningitis development depends, to some extent, on the immunological status of the patients, with immunocompromised patients being the most susceptible (Brown et al., 2013; Twarog and Thompson, 2015; Jackson et al., 2019).

Histoplasma capsulatum is the etiological agent of another endemic mycosis, histoplasmosis. In addition to being rare, the dissemination of *Histoplasma* to the CNS generally occurs in patients with AIDS and other immunosuppression disorders, leading to severe cases of meningitis (Riddell and Wheat, 2019) that are associated with high morbidity and mortality rates (Wheat et al., 2018); however, immunocompetent patients can be affected (Schestatsky et al., 2006). In addition to meningitis, CNS histoplasmosis causes parenchymal mass lesions in the brains or spinal cord, stroke due to cerebral emboli and diffuse encephalitis (Saccante, 2008; Wheat et al., 1990).

The main species responsible for fungal meningitis worldwide is *Cryptococcus neoformans* (Srikanta et al., 2014). In cryptococcal infections, meningitis is the clinical manifestation that has the greatest effect on patients. Even when properly treated, in most cases, this meningitis cannot be ameliorated, and the mortality is approximately 70%, depending to the condition of the patient's immune system and the geographical location (Rajasingham et al., 2017).

On the basis of the highest indices of mortality deriving from brain infection, in this essay, we mostly address the mechanisms used by *Cryptococcus* to disseminate in the body and invade the CNS and discuss some virulence factors associated with the infection of the CNS, elucidating interesting studies that have helped to unravel the fascinating predilection of this fungus for the CNS.

The *Cryptococcus* Genus

The *Cryptococcus* genus includes two important species, *C. gattii* and *C. neoformans*, that infect humans, causing cryptococcosis, an important systemic mycosis with high rates of morbidity and mortality worldwide (Maziarz and Perfect, 2016; Zaragoza, 2019).

Cryptococcus neoformans and *C. gattii* are spherical yeast with buds that each have a polysaccharide capsule that can vary in size among distinct strains (Voelz *et al.*, 2010; Rodrigues *et al.*, 1999; Negroni, 2012). Under the capsule, a rigid and dynamic cell wall consists of pigments, proteins, and polysaccharides that determine cell shape, interaction with other matrix cells, osmotic control, and other important biological processes, such as permeability (Rodrigues *et al.*, 2007, 2008). In nature, these species inhabit different niches. *C. neoformans* can be found in the soil and bird excreta, while *C. gattii* is more likely to be found in eucalyptus trees (Mitchell and Perfect, 1995), as shown in Fig. 3.

Both *Cryptococcus* species are etiological agents of cryptococcosis, a systemic worldwide mycosis able to affect both human and animal individuals (Rodrigues *et al.*, 1999) and to affect both healthy and immunocompromised individuals (Bandalizadeh *et al.*, 2019), as shown in Fig. 3. *C. neoformans* is the major causative agent of cryptococcosis, infecting mainly immunocompromised individuals (Voelz *et al.*, 2010; Rodrigues *et al.*, 1999), displaying a predilection for infecting the CNS, leading to the most severe manifestation of cryptococcosis, cryptococcal meningitis (Rodrigues *et al.*, 2007; May *et al.*, 2016; Bielska and May, 2016). In immunocompetent individuals, *C. gattii* shows the ability to establish cryptococcal infection with a predilection for infecting the lungs, showing elevated pathogenicity that is difficult to treat and is associated with high mortality rates (Brouwer *et al.*, 2007; Voelz *et al.*, 2010; Bielska and May, 2016).

Cryptococcosis starts with the inhalation of *Cryptococcus* spores or small, desiccated and less-encapsulated yeast cells spread in the environment. These are the infectious propagules of an ideal size for alveolar deposition and interaction with resident macrophages. In this first contact with the host, the host defenses will determine the development of the infection (Bielska and May, 2016; Gottfredsson and Perfect, 2000; Rodrigues *et al.*, 1999; Velagapudi *et al.*, 2009).

To evade host defenses and cause systemic mycosis, in addition to producing different virulence factors, *Cryptococci* undergo substantial morphological changes that drive their interaction with hosts (Rodrigues *et al.*, 1999, 2008). Morphological changes are common among fungi; however, *Cryptococcus* morphological changes are unique, as they permit the fungi to significantly increase its size by increasing its capsule, its body or both, becoming so-called titan cells (cells with bodies larger than 15 μm , excluding the capsule) (Zaragoza and Nielsen, 2013). Titan cells are polyploid cells with a thickened cell wall and a dense capsule, and they are important virulence factors because they impair phagocytosis and induce the polarization of the host immune response to promote successful infection (Zaragoza *et al.*, 2008; García-Rodas *et al.*, 2018; Zaragoza *et al.*, 2009).

Cryptococcus interactions with the host are critically influenced by polysaccharides that are produced and mounted into a network composed mainly of glucuronoxylomannan (GXM), glucuronoxylomannogalactan (GXMGal), and mannoproteins that form a capsule surrounding the cell (Rodrigues *et al.*, 1999; Bielska and May, 2016; Rodrigues *et al.*, 2015; Larocque-de-Freitas *et al.*, 2018). The capsule is a distinctive feature of cryptococcal cells that protect the fungus against host immunological defenses

Fig. 3 Transmission of cryptococcal propagules from environmental niches to the human host. *C. neoformans* preferentially affects immunocompromised hosts, while *C. gattii* is an efficient causer of human disease in immunocompetent individuals. For details about the environmental niches of each species, see text. Image credit: Wagner Nagib (Instituto Carlos Chagas, Fiocruz).

during infection (Zaragoza *et al.*, 2006). The *Cryptococcus* capsule can be visualized by microscopy, and Fig. 4 shows different techniques to visualize this structure, such as India-ink staining, immunofluorescence, and electron microscopy.

Capsule components are synthesized in the cytoplasm and released to the extracellular space by extracellular vesicles (EVs) (Bielska and May, 2016). These particles are efficient carriers of molecules, such as lipids, pigments, polysaccharides, proteins,

Fig. 4 Microscopic examination of the cryptococcal capsule. Panels A, C and E illustrate *C. neoformans* cells, while panels B, D and F illustrate *C. gattii*. Capsular structures can be evidenced by counterstaining with India ink (A–B), immunofluorescence (C–D, where the blue fluorescence denotes the cell wall after staining with calcofluor-white and the red fluorescence represents the capsule after antibody staining) and scanning electron microscopy (E–F).

toxins, nucleic acids, and other virulence factors, to the extracellular environment (Herkert *et al.*, 2019; Coelho and Casadevall, 2019). EV size and cargo may also affect the fungi–host interactions by delivering toxins to the host and affecting antimicrobial resistance (Coelho and Casadevall, 2019; Herkert *et al.*, 2019).

In addition to their morphological changes, other important virulence factors must be considered, such as melanin deposition into the cell wall, lipids, phospholipase, urease, and laccase, in addition to the ability to grow at mammalian temperatures (Rodrigues *et al.*, 1999, 2007; Bielska and May, 2016; Janbon, 2004). Altogether, these factors result in a great ability to manipulate the host immune system and cause life-threatening CNS infection both in immunocompetent and immunocompromised individuals, making it an important worldwide health and economic problem.

Cryptococcosis Epidemiology

Epidemiological data show that the majority of cryptococcal disease cases occur among immunocompromised individuals (Nyazika *et al.*, 2018), with HIV infection presenting as the main risk factor and accounting for 95% of the cases in middle- and low-income countries and 80% of the cases in high-income countries. Individuals taking immunosuppressive drugs constitute most of the remaining cases, although immunocompetent patients can also be affected in some settings (Sloan and Parris, 2014; de Azambuja *et al.*, 2018). Given the differences in HIV endemic status and geographic and ethnic factors, cryptococcosis numbers can vary greatly between different countries and regions, ranging from 6.6 cases per million in Australia to 15.6 per 100,000 in the Gauteng Province of South Africa (Fang *et al.*, 2015).

At the peak of the HIV pandemic, more than 600,000 deaths were estimated to have occurred globally as a result of cryptococcosis (Park *et al.*, 2009). France reported a fivefold increase in cryptococcosis from 1985 to 1993, while the number of cases in patients not infected with HIV remained stable. Of the 517 reported cases in New York City in 1991, 96% were related to HIV (Sloan and Parris, 2014). Although this number was greatly reduced as access to effective antiretroviral therapy expanded in developed countries, cryptococcosis continued to have a great impact on immunocompromised individuals, mainly in sub-Saharan Africa and low- and medium-income countries of middle Southeast Asia (Nissapatorn, 2008) and Latin America (Leimann and Koifman, 2008), where mortality rates could be as high as 70% (Leimann and Koifman, 2008).

C. gattii was previously prevalent in subtropical and tropical regions, spreading to temperate zones and affecting the Vancouver Island, British Columbia (218 cases during 1999–2007) (Galanis *et al.*, 2010), and the northwestern US states of Washington and Oregon (96 cases reported to the CDC between December 2004 and July 2011) (Harris *et al.*, 2011). Evidence suggests that the outbreak is expanding along the US West Coast (Applen Clancey *et al.*, 2019). Data from studies conducted in Australia, Papua New Guinea, British Columbia, Canada, and the US Pacific Northwest point to a mortality rate ranging from 13 to 33%, depending on differences in treatment, time of follow-up and patient characteristics (see “Relevant Websites section”).

In addition to outbreaks in previously unaffected regions, another important fact to consider is the epidemiological change currently observed in medium- and high-income countries, attributed to the effectiveness of HIV diagnosis and treatment, skewing cryptococcosis susceptibility data and highlighting other susceptible populations. For example, between 1992 and 2007, in Atlanta and Houston in the United States, diabetes was found to be the most common underlying condition associated with cryptococcal infection. In Ottawa, Canada, data from 2005 to 2017 revealed that the most common underlying condition associated with cryptococcosis was hematological malignancies and, considering the fatality rates, solid organ transplantation was also considered an important risk factor (Patel *et al.*, 2019).

Cryptococcosis represents approximately 8% of the invasive fungal infection cases among solid organ transplantation recipients, being the third most common fungal infection in these patients, with an overall incidence ranging from 0.2% to 5%. Among the types of organs transplanted, the lung is associated with an increased risk of cryptococcosis (Baddley *et al.*, 2019). In patients with malignancies, lymphomas were the most common predisposing conditions (66%), followed by leukemias (29%) and myelomas (4%) (Schmalzle *et al.*, 2016).

Sex also seems to have had a role in the epidemiology of cryptococcosis. Curiously, men are affected by cryptococcosis more frequently than women with the disparity present both in HIV⁺ (~8 M:2F) and HIV[−] (~3 M:1F) subjects. In addition to being male as a predisposing risk factor, men affected by cryptococcosis also have more severe symptoms and poorer outcomes (Guess *et al.*, 2018). Although the mechanisms involved in this trend have not been completely elucidated, it seems that hormones may play a role in influencing both the immune response and *Cryptococcus* virulence (McClelland *et al.*, 2013).

With respect to CNS infection, cryptococcal meningitis (CM) is the most common cause of adult meningitis in large parts of the world with high rates of HIV infection. Cryptococcosis is considered, after tuberculosis, the most common cause of illness in people living with HIV/AIDS, being responsible for 15% of the AIDS-related deaths globally. Approximately 200,000 cases are estimated to occur worldwide every year (see “Relevant Websites section”), culminating in 181,000 deaths, of which 73% occur in sub-Saharan Africa (Rajasingham *et al.*, 2017). The management of CM is complicated by the fact that, in several locations, one-half of the patients present with a medical history of antiretroviral therapy (ART) combined with persistently low CD4 + T cell counts due to loss of follow-up, treatment non-adherence or development of resistance to therapy (Williamson *et al.*, 2017).

Although globally associated with HIV cases in developed countries, the prevalence of CM is also increasing in populations not infected with HIV, such as solid organ transplantation recipients, patients with rheumatic diseases, and those receiving immunosuppressive therapies (Beardsley *et al.*, 2019).

Regarding the CM 1-year mortality rate worldwide, the numbers generally reflect country income level. In low-income patients, mortality ranges from 70% for patients in care to 100% for patients not in care. In the medium income category, mortality is

approximately 40% and 60% of all in-care and not-in-care patients, respectively; specifically, in Europe, it is 30 and 45%, and in North America, it is 20% and 30% (de Azambuja *et al.*, 2018; Rajasingham *et al.*, 2017).

Cryptococcus “Travels” to the Brain

Cryptococcus can disseminate and reach the CNS due a specific tropism for this site (Santiago-Tirado *et al.*, 2017). The CNS environment confers an immune privilege condition to the fungi that is related to the lack of a robust inflammatory response against antigenic changes (Santiago-Tirado and Doering, 2017; Vestweber, 2015). The first step required to reach and invade the CNS is to interact with endothelial cells and then pass through the BBB that protects the host against invaders or toxic compounds (Weiss *et al.*, 2009; Kim, 2008).

The structure of the BBB is composed of an endothelial cell layer with tight junctions and microcapillary blood vessels, representing the interface between the peripheral circulation and CNS. The BBB is highly selective for drug and microorganism permeation due to the action of efflux transporters, restrictive passive diffusion, absence of gaps and paracellular permeation (Daneman and Prat, 2015). To reach the CNS, *Cryptococcus* uses three routes, known to occur concomitantly: (1) inside infected phagocytes and possibly neutrophils (Trojan horse model) (Santangelo *et al.*, 2004; Shi *et al.*, 2010; Charlier *et al.*, 2009), (2) penetration between the cell barriers with or without disruption of the BBB endothelial cell tight junctions (paracellular model), and (3) crossing through the microvasculature as free fungi (transcellular model). Fig. 5 illustrates each mechanism.

Trojan Horse Model

In the Trojan horse mechanism, *Cryptococcus* parasitizes phagocytes and survives within them, using these cells as vehicles to reach the brain (Zaragoza, 2019; Casadevall, 2010). Evidence that *Cryptococcus* can disseminate to the CNS through Trojan horse mechanisms was obtained from macrophage depletion studies in which the results showed a reduction in BBB invasion (Cheng *et al.*, 2009). Additionally, several studies have pointed to the occurrence of this phenomenon in vivo. First, monocyte depletion in mice before *Cryptococcus* infection resulted in a reduction in disease severity and in fungal burden (Charlier *et al.*, 2009). Second, the transfer of macrophages and monocytes from mice infected with *Cryptococcus* to healthy animals caused cerebral cryptococcosis. Finally, intravenous infection of mice with macrophages infected with ingested cryptococcal cells led to cryptococcal meningoencephalitis (Santangelo *et al.*, 2004; Charlier *et al.*, 2005). Indeed, Santiago-Tirado *et al.* (2017) demonstrated that cryptococcal cells inside phagocytes cross the BBB. Once in the brain, *Cryptococcus* can be expelled from the phagocytes through a mechanism called vomocytosis, a nonlytic process that represents the end of the Trojan horse route (Taylor-Smith and May, 2016), spreading the cells to the CNS.

Paracellular Model

This route of brain infection involves crossing the BBB through intercellular spaces with or without tight junction damage. Olszewski *et al.* (2004) demonstrated that *C. neoformans* had the ability to cross the BBB, showing fungal colocalization in

Fig. 5 Brain invasion by cryptococci. The three major mechanisms illustrating how cryptococci leave the blood to cross the endothelial layer and colonize the brain tissue are illustrated. For details, see related text. Image credit: Wagner Nagib (Instituto Carlos Chagas, Fiocruz).

capillaries and damaged endothelial cells. The same paracellular entry was verified by Charlier *et al.* (2005). Additionally, differences related to the capsule and size of the yeast could be involved in the damage to the endothelium. During infection, *Cryptococcus* induces host cell cytoskeleton changes; fungal adhesion promotes the dephosphorylation of cofilin and occludin, two proteins involved in cytoskeleton integrity, resulting in actin rearrangement and alterations in tight junction integrity that can facilitate the paracellular route of entry into the CNS (Chen *et al.*, 2003). Another possible route of paracellular entry by *Cryptococcus* relates to its ability to subvert host plasminogen by converting it into plasmin, a serine protease with proteolytic activity that can promote disruptions to the host membrane and extracellular matrix, thus weakening tight junctions and facilitating fungal invasion of the CNS (Stie *et al.*, 2009; Stie and Fox, 2012).

Transcellular Model

CNS invasion by transcytosis involves the endocytosis processes and requires that cryptococci adhere to endothelial cells before entering into brain tissue. Chang *et al.* (2004) demonstrated that, during the interaction of *Cryptococcus* with human brain microvascular endothelial cells (HBMECs) and after fungal adhesion to host cells, endothelial cells form microvillus-like projections that engulf the yeast cell; additionally, they verified the presence of free yeast inside the brain parenchyma near the capillaries, demonstrating the transcellular passage of *Cryptococcus* through the BBB. Charlier *et al.* (2005) reported the presence of yeast at cortical capillaries without the involvement of the choroid plexus at early stages after *Cryptococcus* infection and detected the damage to endothelial layers (Charlier *et al.*, 2005); in addition, the yeast crossed the HBMECs without affecting HBMEC integrity.

The association of hyaluronic acid (HA), produced by *Cryptococcus*, with CD44, the receptor in lipid rafts of endothelial cells, was described as important to the entry of the fungus at HBMEC membrane rafts since it can induce protein kinase alpha (PKC- α), which contributes to host cytoskeleton reorganization and phagocytosis (Chang *et al.*, 2006; Jong *et al.*, 2008).

CD44, an HBMEC cell surface protein, has been in fact identified as a *C. neoformans* receptor. The association of (HA), with CD44 increased the presence of this molecule in lipid rafts of HBMEC during fungal engagement. This recruitment generated docking sites for a subsequent yeast engulfment. The association of *C. neoformans* with HBMEC was followed by the activation of protein kinase alpha (PKC- α), which contributed to host cytoskeleton reorganization and phagocytosis (Chang *et al.*, 2006; Jong *et al.*, 2008). Indeed, the interaction of *Cryptococcus* with HBMECs triggered the activation of other host signaling proteins relevant to cytoskeleton rearrangement, impacting fungal transmigration. Among the host proteins activated, Rho GTPases can phosphorylate other host proteins, such as FAK, PKC α and ezrin (Kim *et al.*, 2012), promoting cytoskeleton remodeling tight junctions modulation. Another signaling pathway that likely contributes to cryptococcal transmigration is that involving the EPH-EphrinA1 (EphA2) tyrosine kinase receptor, which, when activated via CD44, triggers changes in membrane permeability, promoting the weakening of tight junctions through the activity of Rho, Rac and Cdc42. Inhibition of EphA2 resulted in the prevention of transmigration; in contrast, endothelial cell treatment with an EphA2 agonist, a ligand of EphA2, resulted in enhanced *C. neoformans* transmigration (Aaron *et al.*, 2018).

Cryptococcus “Passport” to Brain Travel

Both fungal and host factors have been identified to be involved in CNS invasion. Some virulence factors are described as being important to *Cryptococcus* infection and are shared by both pathogenic species, such as phospholipase B1 (Plb1) and laccase, which are related to fungal egress at the initial site of infection (lungs) and dissemination into the CNS (Noverr *et al.*, 2004; Santangelo *et al.*, 2004), and Plb1 and urease in the crossing of the blood–brain barrier (Santangelo *et al.*, 2004; Shi *et al.*, 2010).

Inositol

Cryptococcus CNS predilection is not yet fully understood. However, some evidence points to inositol involvement. Inositol is a carbocyclic sugar that is found at higher levels in the brain, where it acts as an osmolyte. *Cryptococcus* has also developed ways to acquire inositol, using it as a carbon source, thus influencing brain infection. The availability of inositol to fungal cells can be influenced by the induction of *Cryptococcus* alterations in the tight junctions between endothelial cells, which leads to an increase in inositol permeability and increasing levels of inositol that enhance *Cryptococcus* transmigration in a species-specific way; inositol does not influence the transmigration of *C. albicans* (Liu *et al.*, 2013).

Inositol acquisition occurs through a specific system comprised of the transporter gene (*ITR*) family, mainly the *Itr1a* and *Itr3c* transporters. Mutations in these transporters led to a significant reduction (50%) in BBB transmigration in vitro when compared to the wild-type strain. In vivo, defects in inositol acquisition correlated with reduced fungal burden and lesions in the brain (Liu *et al.*, 2013). Exposure of *Cryptococcus* to inositol leads to an increase in the expression of a hyaluronic acid synthase that can associate with CD44 in endothelial cell membrane lipid rafts to enhance the invasive potential of *Cryptococcus* (Jong *et al.*, 2012; Liu *et al.*, 2013). The inhibition of inositol transporters reduced the inositol uptake and impaired the crossing of *Cryptococcus* through the HBMEC monolayer (Liu *et al.*, 2013). Finally, strains lacking *ITR1a* and *ITR3c* inositol transporters evoked a more

pronounced protective immune response and had reduced levels of GXM secretion in the presence of inositol as carbon source (Liu *et al.*, 2014).

Urease

Urease is a metalloenzyme evenly distributed in the human body, including in the CNS, responsible for catalyzing the hydrolysis of urea into carbon dioxide and ammonia, the latter of which can be protonated to form ammonium, resulting in an increase in pH with consequences to pathogen-host interaction (Rutherford, 2014).

Urease improves the ability of *Cryptococcus* to invade the CNS. Mice infected with a mutant strain lacking urease showed a reduced brain fungal burden when compared to the load in the wild type mice (Olszewski *et al.*, 2004). Urease can directly affect the *Cryptococcus*–host BBB interaction. The ammonia generated due to urea hydrolysis can elicit both direct toxic effects in endothelial cells, promoting BBB disruption (“opening” the endothelial cell junctions) and resulting in increased permeability to cells, which facilitates brain invasion (Stamatovic *et al.*, 2008) and the induction of adhesion molecules at the endothelial surface (Olszewski *et al.*, 2004).

Fu *et al.* (2018) infected mice with macrophages containing urease-positive and urease-negative strains and compared the fungal burden in the lungs and brain. Differences were observed only in fungal recovery from the brain with a reduced number of viable urease-negative strains. Knowing that *Cryptococcus* can cross the BBB through the Trojan horse mechanism or transcytosis of endothelial cells, the authors suggested that cryptococcal urease enabled the fungus to persist in the phagocytes and thus be transported to the brain, where it is likely released through the induction of nonlytic exocytosis.

Phospholipase B1

Phospholipase B (PLB1) facilitates *C. neoformans* adhesion to host cells, replication, and survival within macrophages (Ganendren *et al.*, 2006; Santangelo *et al.*, 2004; Noverr *et al.*, 2003). Because of its hydrolytic activity on ester linkages in glycerophospholipids found abundantly in the host cell membrane and in pulmonary surfactants (Djordjevic, 2010), PLB1 contributes to the invasion and dissemination processes of fungus (Cox *et al.*, 2001; Noverr *et al.*, 2003) by breaking down host membranes and contributing to fungi escape from phagolysosomes (Wright *et al.*, 2007).

Rearrangement of host cell actin is related to the internalization process for several pathogens (Munoz-Duarte *et al.*, 2016; Mendes-Giannini *et al.*, 2004). During *Cryptococcus* transmigration to the brain, remodeling of the host endothelial cell cytoskeleton occurs, with fingerlike projections (microvilli) of actin surrounding intracellular yeast (Maruvada *et al.*, 2012) without altering host cell integrity (Chang *et al.*, 2004). *Cryptococcus* PLB1 participates in the activation of an important molecule involved in actin cytoskeleton dynamics, Rac1, which belongs to the small Rho GTPase family (Sepp and Auld, 2003; Noverr *et al.*, 2003). *Cryptococcus* mutant strains lacking PLB1 showed lower Rac1 activation levels in endothelial cells, leading to a significant reduction in *Cryptococcus* transmigration and fungal burden in the brain (Noverr *et al.*, 2003).

Laccase

The functions of laccase in *C. neoformans* include protection against macrophage antifungal activity through the production of melanin, iron oxidation products, and prostaglandin E2 (PGE2) (Liu *et al.*, 1999a; Eisenman *et al.*, 2007). Laccase can oxidize catecholamine substrates (dopamine, norepinephrine, and epinephrine) to generate melanin during infection (Liu *et al.*, 1999b), and melanin has the potential to alter host cell defense (Montine *et al.*, 1997). Melanins are polyphenolic and/or polyindolic pigments that can be produced by several pathogens and are frequently related to the pathogenicity (Lee *et al.*, 2019). When comparing melanized and nonmelanized yeast strains, several studies have concluded that melanin can protect the fungus against oxidant agents, microbicidal peptides, phagocytosis, and killing by macrophages and that melanin confers particular resistance to antifungals (Wang *et al.*, 1995; Liu *et al.*, 1999a; Wang and Casadevall, 1994; Jacobson and Tinnell, 1993), acting as a free radical scavenger (Porebska-Budny *et al.*, 1992). The presence of fungal melanin *in vivo* was first detected in tissues from patients with AIDS and cryptococcal meningoencephalitis (Nosanchuk *et al.*, 2000). The ability of the fungus to produce melanin from catecholamines was associated with the neurotropism of *Cryptococcus* (Polacheck *et al.*, 1982) Qiu *et al.* (2012). A mutant strain lacking laccase was unable to disseminate from the lungs to the CNS, leading to a nonprotective polarization of the host immune response.

Metalloprotease 1 (Mrp1)

Mrp1 belongs to the M36 peptidase class. It is upregulated during CNS infection and secreted by *C. neoformans* during the infectious process (Steen *et al.*, 2003; Vu *et al.*, 2014). Mutant strains lacking Mrp1 had a decreased ability to adhere to endothelial cells and to transmigrate through the host BBB (Vu *et al.*, 2014). In addition, in mice infected with a mutant yeast strain lacking Mrp1 the brain fungal burden was significantly reduced, suggesting the involvement of Mrp1 in the BBB transmigration process (Vu *et al.*, 2014). Interestingly, Na Pombejra *et al.* (2017) showed that *Cryptococcus* Mrp1 expressed in *Saccharomyces cerevisiae* led to nonpathogenic fungi crossing the BBB model *in vitro* without any damage to tight junctions. They also found that *Cryptococcus*

Mrp1 interacts with several endothelial cell surface proteins, most of which were related to membrane and cytoskeleton rearrangement.

Antifungal Alternatives for Treating Cryptococcal Meningitis

The treatment of fungal infections continues to be a challenge. The limited antifungal arsenal is related to the similarity between fungal and human cells, leading to serious toxicity and difficulty in the search for new targets (Perfect, 2017). Another obstacles for mycosis treatment are the high cost, narrow spectrum of action and low bioavailability of the currently available antifungals (Denning and Bromley, 2015). Currently, the available antifungal drugs are classified into four classes: (1) inhibitors of membrane ergosterol biosynthesis (azoles, triazoles, and allylamine); (2) compounds affecting membrane stability (polyenes); (3) inhibitors of cell wall and β -glucan synthesis (echinocandins); and (4) anti-metabolite action (5-fluorocytosine, 5-FC).

The recommended treatment regimen for cryptococcosis in HIV patients is composed of three steps: induction therapy, consisting of the combination of amphotericin B (AmB) and 5-FC for 2 weeks; next, this treatment set is consolidated with fluconazole (8 weeks); and finally, maintenance therapy consists of fluconazole (FLZ) (until the immunodeficiency is reverted). Alternatives to this treatment regimen are also described in Fig. 6 (Perfect et al., 2010).

AmB is a fungicidal compound belonging to the polyene class, and its mechanism of action is the formation of pores in the fungus cell membrane causing the loss of ions and sugars and, as a consequence, osmotic imbalance; however, it has been proposed that the mechanism of action involves the production of reactive oxygen species and immune response modulation (Walsh et al., 2008; Sangalli-Leite et al., 2011; Mesa-Arango et al., 2012; Perfect, 2017). *Cryptococcus* resistance to AmB is rare (Kelly et al., 1994; Nolte et al., 1997); however, this antifungal agent has high toxic effects, especially nephrotoxicity (de Souza et al., 2016).

5-Fluorocytosine (5-FC) inhibits nucleic acid (DNA and RNA) synthesis by incorporating 5-FC metabolites, which have a molecular structure analogous to pyrimidines (Odds et al., 2003; Perfect, 2017). 5-FC treatment is recommended during CM in combination with AmB. The use of this combination decreases the risk of CM relapse and promotes a faster clearance of *Cryptococcus* spp. from the cerebrospinal fluid compared to AmB alone (Day et al., 2013).

Belonging to the triazole class, fluconazole (FLZ) has as mechanism of action that involves the inhibition of the 14- α demethylase enzyme (encoded by the *ERG11* gene), which is critical for converting lanosterol to ergosterol (Perfect, 2017). Different studies reported the resistance of *Cryptococcus* spp. to FLZ, with efflux pumps and *ERG11* gene mutations responsible for this phenotype. In special cases, such as intolerance to FLZ, other triazoles and itraconazole can be used during consolidation therapy; however, these alternative antifungal agents have poor aqueous solubility and poor oral bioavailability, which means that their levels must be monitored in the serum (Perfect et al., 2010; Kale and Johnson, 2005).

Cryptococcus spp. cause meningitis mainly in HIV-infected individuals in an advanced stage (CD4 cell count <200 cells/mm³), and the introduction of antiretroviral therapy (ART) was an important milestone for the reduced mortality incidence rate of this mycosis in

Fig. 6 Therapeutic protocols for fighting cryptococcal disease. AmBd, deoxycholate amphotericin B; 5-FC, fluorocytosine; ABLC, amphotericin B lipid complex.

developed countries (Mirza *et al.*, 2003; Antinori *et al.*, 2009). However, in limited-resource counties where late HIV diagnosis and limited access to treatment is prevalent, the number of deaths caused by cryptococcal meningitis are still alarming (Rajasingham *et al.*, 2017). Moreover, recommended induction treatment (AmB plus 5-FC) is not available in most African clinical centers, and FLZ is often the only drug available (Roemer and Krysan, 2014).

With the unavailability of the induction treatment in resource-limited settings, only monotherapy intervention can be performed, and the use of FLZ at 400 mg/kg as monotherapy is related to inefficacy (Lightowler *et al.*, 2010). However, good outcomes have been described for FLZ ranging from 800 to 2000 mg/daily (Milefchik *et al.*, 2008). To control residual infection, high-dose FLZ (800 mg/day) was also described as an option during consolidation therapy and has been recommended as an alternative by the World Health Organization HIV management guidelines (after short-course induction with amphotericin for 5–7 days) (Murphy *et al.*, 2018). A recent study demonstrated that the use of high fluconazole doses can kill a susceptible population of yeast but can also cause emerging fungal resistance, which is associated with the development of aneuploidy (Hope *et al.*, 2019).

Aiming for treatment optimization, a review of clinical trials reported the evidence of effectiveness treatment for *Cryptococcus* meningitis by comparing the following antifungal regimens: FLZ to FLZ with 5-FC; AmB to AmB with 5-FC; AmB given alone to AmB given with 5-FC and FLZ alone; high to standard dose AmB with 5-FC; and AmB to liposomal AmB; however, no evidence was found to consider one treatment superior to any other (Sloan *et al.*, 2008). Recently, in a meta-analysis study that investigated 13 trials with a total of 2426 participants and compared 21 antifungal therapy interventions (July 2014 to July 2018), the authors concluded that the combination of AmB deoxycholate and 5-FC therapy for one week is a promising treatment alternative for the treatment of cryptococcal meningitis in HIV patients in limited-resource conditions. Moreover, the combination of 5FC and FLZ for two weeks, administered orally, may be an alternative for AmB deoxycholate or when intravenous therapy is unavailable (Tenforde *et al.*, 2018).

CM also affects HIV-negative immunocompromised patients (e.g., solid organ transplantation). In these cases, the treatment regimen is similar to the recommended regimen for HIV-infected individuals. Moreover, important considerations, such as the immunocompromised state, antifungal response, presence of neurological complications, therapy cost and toxicity, should be taken into account (Henao-Martinez *et al.*, 2018). An alternative treatment for CM in patients not infected with HIV but with refractory infection or intolerance to other antifungal drugs is therapy with fluconazole 800 mg/day; however, the data on this therapeutic regimen are scarce, and this treatment needs further investigation (Zhao *et al.*, 2018).

Alternatives to CM treatment also have been studied. The antidepressant sertraline (selective serotonin reuptake inhibitor) is one example. The in vitro and in vivo antifungal activity and synergistic activity of sertraline with other antifungals have been described (Trevino-Rangel Rde *et al.*, 2016; Rossato *et al.*, 2016; Zhai *et al.*, 2012). However, a phase 3 clinical trial did not find benefit for the use of sertraline as a therapeutic component, and this trial was terminated (Rhein *et al.*, 2019). Other treatment strategies include use of natural product derivatives (Li *et al.*, 2019a,b), administration of vaccines (Hester *et al.*, 2019) and extracorporeal filtration of yeast from cerebrospinal fluid to reduce the fungal burden (neurapheresis therapy) (Smilnak *et al.*, 2018).

Fungal Cardiac Infections

Candida Species

Candida is a genus of yeasts that are part of the normal skin and gut flora, and are common colonizers of the genitourinary tract. They can be detected on the mucosal surfaces of 50%–70% of healthy individuals. *Candida* are common sources of nosocomial infections. While the genus encompasses at least 15 pathogenic species, *C. albicans*, *C. glabrata*, *C. tropicalis*, *C. parapsilosis*, and *C. krusei* are responsible for ~ 95% of invasive diseases. Candidemia occurs when the host is immunocompromised, has a breach of the protective mucosal barriers, or has had prolonged antibiotic use (McCarty and Pappas, 2016; Pappas et al., 2018). *C. albicans* remains the most common pathogenic *Candida* spp. Otherwise, the second most common pathogenic species varies widely between regions, medical centers, and intensive care units with *C. glabrata* or *C. parapsilosis* being the most frequently encountered species. In the United States and northwestern Europe, *C. glabrata* is the second most common species isolated (Pfaller et al., 2011). We will be focusing on *C. albicans* and briefly touch on other relevant *Candida* species.

Pathogenesis

As mentioned above, there are three disposing factors for candidemia. Immunosuppression, particularly neutropenia, is a major risk factor for disease as is the bypassing of mucosal barriers. The mechanisms for prolonged antibiotic use increasing risk is through the removal commensal gut microbiota species that secrete protective factors that suppress *Candida* overgrowth (Fan et al., 2015). *C. albicans* undergoes morphogenic transition between a unicellular yeast form and a multicellular, filamentous pseudo-hyphae and/or hyphae form. This dimorphism helps the organism evade the immune system as different states have distinct cell surface and wall compositions. Strains that are locked to one form have impaired virulence in mice model (Lo et al., 1997). *C. albicans* also effectively adheres to endothelial and epithelial cells through the expression of adhesins along with the secretion of proteases and phospholipases, which also help with biofilm formation and tissue invasion (Schmidt et al., 2012; Felk et al., 2002). Neutrophils play the most important role in controlling invasive candidiasis. While monocytes and macrophages have mildly less *Candida* killing capacity, they confer lymphocyte-independent memory that provides protection from future infections (Lionakis et al., 2013).

Endocarditis

Candida endovascular infections usually manifests as endocarditis, which is an infection of the inner lining of the heart chambers and heart valves, or infection of a implanted device such as a pacemaker (McCarty and Pappas, 2016). *Candida* endocarditis is the most common form of fungal endocarditis with *C. albicans* being the most prevalent (24%) and the non-*albicans Candida* combining to represent the second most common etiology (28%) (Ellis et al., 2001). In an observational cohort study of 70 confirmed *Candida* endocarditis cases, the most common species isolated were *C. albicans* and *C. parapsilosis*, where the latter tended to develop in diabetic patients and were community acquired (Arnold et al., 2015). Overall, half the infections were hospital acquired, and about a quarter were community acquired. The biggest risks factor for endocarditis was the presence of a prosthetic heart valve (46%) in which there was a 36% in-hospital and a 59% 1-year mortality rate. In the same study, congestive heart failure, embolization, and intracardiac abscess were the most common complications (Arnold et al., 2015).

The clinical presentation of *Candida* endocarditis typically consists of fever, major peripheral emboli (i.e., ischemic limb), and cardiac murmur (Ellis et al., 2001). Both the Infectious Diseases Society of America (IDSA) 2016 candidiasis guideline and American Heart Association 2015 infective endocarditis guideline recommend combined antifungal and valve replacement therapies (Pappas et al., 2015; Baddour et al., 2015). Notably, some studies have found no statistically significant mortality benefit between medical vs medical and surgical treatment (Rivoisy et al., 2017; Arnold et al., 2015).

Myocarditis

Since the routine use of immunosuppressive medications, *Candida* have been the most prevalent cause of fungal myocarditis, an infection of the heart muscles, which occurs in 10%–60% in patients with disseminated candidiasis (Frenkel, 1962; Gruhn and Sanson, 1963; Walsh et al., 1980). In 1968, a cardiac autopsy report of 420 acute leukemia patients identified a prevalence of *Candida* myocarditis of 1.4%, while there was only one identified *Candida* (named “Torulosis”) myocarditis in the 1402 cases during American military autopsies performed over the course of World War II (Gore and Saphir, 1947; Roberts et al., 1968). In *Candida* myocarditis, histological findings primarily show myocardial abscesses with random distribution, which is consistent with hematogenous dissemination patterns (Franklin et al., 1976). *C. albicans* is the most common *Candida* species causing myocarditis, followed by *C. parapsilosis*, which is frequently associated with endocarditis (Pfaller et al., 1998). Of note, pathogenesis of

myocarditis in the setting of *Candida* endocarditis is not an extension of the endocarditis vegetation itself, but myocardial abscess can progress to involve the endocardium (Atkinson *et al.*, 1984a,b).

Risk factors identified from multiple autopsy reviews include prolonged antibiotic therapy, corticosteroid administration, malignancy, autoimmune diseases, history major operations, central venous catheters, and intravenous (IV) drug use (Walsh *et al.*, 1980; Gaines and Remington, 1972; Franklin *et al.*, 1976; Hofman *et al.*, 1992). Cooccurrence rates with endocarditis range from 16% to 71% (Rubinstein and Lang, 1995; Walsh *et al.*, 1980; Parker, 1980; Atkinson *et al.*, 1984a). Franklin *et al.*'s case series from 1959 to 1974 of 31 confirmed post-mortem revealed that 59% of the cases had T-wave abnormalities, 23% with supraventricular arrhythmia, 14% with atrial-ventricular block, and only 1 case had normal ECG. Diagnosis can be difficult as blood cultures were only positive in 61% of confirmed *candida* myocarditis cases. Hypotension or shock occurred in 42% of the myocarditis cases. *Candida* is not a frequent invader of the blood vessels, but case reports have documented angioinvasion resulting in myocardial infarction (Franklin *et al.*, 1976; Van Kirk *et al.*, 1974; Atkinson *et al.*, 1984a). It is hard to pinpoint the mortality rate of *candida* myocarditis as the vast majority of reports are postmortem.

Aspergillus Species

Overview

This is a genus of mold that encompasses hundreds of species. *Aspergillus fumigatus* and *Aspergillus flavus* are the most common species to cause invasive diseases, primarily in immunocompromised individuals. *Aspergillus* endocarditis is second to *Candida* endocarditis with a ~20% prevalence (Ellis *et al.*, 2001; Pierrotti and Baddour, 2002). The overall rising trend in invasive aspergillosis (IA), along with invasive candidiasis, correlates with the increased use of immunosuppressive medications, antibiotics and invasive procedures (Nosanchuk, 2002).

Pathogenesis

Aspergillus inhabits decaying materials in the environment. The primary mode of infection is through inhalation of its asexual spores, the conidia. These spores are usually cleared by alveolar macrophages and neutrophils, but they may successfully evade killing and germinate into hyphae. Neutrophils are the dominant cells that eliminate hyphae from tissue. Indeed, neutropenia and corticosteroid-induced immunosuppression are the predisposing factors responsible for IA. IA in neutropenia is characterized by angioinvasion from unchecked hyphae growth that leads to thrombosis and hemorrhage (Stergiopoulou *et al.*, 2007). Corticosteroid-induced immunosuppression more often results in non-angioinvasion due to intact neutrophil presence, despite corticosteroid's many effects on phagocytosis and cytokine production, while lung tissue injuries are from local inflammation (Lionakis and Kontoyiannis, 2003; Dagenais and Keller, 2009).

Endocarditis

Aspergillus endocarditis (AE) is typically associated with underlying cardiac abnormalities and cardiac procedures such as prosthetic valve placements (Pierrotti and Baddour, 2002). Clinical presentation typically consists of fever, major peripheral emboli (i.e., ischemic limb), and cardiac murmur (McCormack and Pollard, 2011). Osler's nodes or Janeway lesions are not usually seen (Rubinstein and Lang, 1995). Meshaal *et al.* observed in a series of 374 AE cases that a lack of fever, acute limb ischemia at presentation, aortic abscess, and prosthetic valve vegetation were strong predictors for AE (Meshaal *et al.*, 2018). Peripheral emboli often turn into mycotic aneurysms due to the angioinvasive nature of *Aspergillus* spp.

Diagnosis for *Aspergillus* endocarditis has been difficult as blood cultures are usually negative, and many cases are diagnosed post-mortem (Antinori *et al.*, 2014). *A. fumigatus* prosthetic valve endocarditis is usually presumptively diagnosed by positive serum (1, 3)- β -D-glucan (BDG) and galactomannan (GM) testing (McCormack and Pollard, 2011). A Cochrane review concluded serum galactomannan sensitivity and specificity at 0.78 and 0.85, respectively, for AE (de Heer *et al.*, 2019; Cruciani *et al.*, 2015). Meanwhile, PCR sensitivity and specificity were comparable at 80.5% and 78.5%, respectively (Cruciani *et al.*, 2015). Mortality rates for AE vary with reports of 68%–100% (McCormack and Pollard, 2011; El-Hamamsy *et al.*, 2005) with average survival length of 11 days (Ellis *et al.*, 2001).

The first line treatment for AE is voriconazole. For patients who cannot tolerate voriconazole, lipid formulation of amphotericin B or isavuconazole can be used (Marr *et al.*, 2015). For monotherapy resistant diseases, there is evidence that echinocandin and amphotericin combination can improve survival (Kontoyiannis *et al.*, 2003). Valve replacement is recommended as adjunct therapy, but surgical results are disappointing.

Myocarditis

In 1984, Atkinson *et al.* reviewed 3801 autopsies of immunocompromised patients and found 8 patients with *Aspergillus* myocarditis. In a following autopsy of just cardiac fungal infections in 60 patients, the author discovered another 8 cases of

Aspergillus myocarditis (Atkinson *et al.*, 1984a,b). Xie *et al* found *A. fumigatus* was the most common species (44%), followed by *A. flavus* (38%) and *A. terreus* (5%) (Xie *et al.*, 2005).

Risk factors for aspergillosis included chemotherapy, broad-spectrum antibiotics, corticosteroids, cardiac surgery, and AIDS (47, 170). Pathogenesis of *Aspergillus* myocarditis differs from *candida* myocarditis as it occurs with *Aspergillus* invading the pulmonary vessels followed by ascending infection into the endocardium and myocardium, direct invasion from the endocarditis vegetation, or hematogenous seeding (Young *et al.*, 1970; Zimmerman, 1950; Walsh and Hutchins, 1979; Buchbinder and Roberts, 1972; Welsh and Buchness, 1955). Because of angioinvasion, *Aspergillus* myocarditis usually presents with myocardial infarction in which approximately 15% of infarctions have accompanied ECG changes (Williams, 1974). Complications include arrhythmias, cardiac tamponade, heart block, and congestive heart failures (Carbone *et al.*, 1964; Nosanchuk, 2002). Diagnosis is often delayed due to negative blood cultures, with Xie *et al* observing that 12% of cases had positive blood cultures. Mortality is high, as most literatures are autopsy reviews. Mortality among AIDS patients is 100% (Xie *et al.*, 2005). Medical therapy for myocarditis is the same as for AE.

Histoplasma Capsulatum

Histoplasma capsulatum is one of the endemic dimorphic fungi. It is the most common cause of fungal pneumonia, but it is an infrequent cause of endovascular infections including endocarditis. This fungus exists as a mold in the soil, and, at 37°C and in tissues, it converts into yeast form. The fungus is endemic in Mississippi and the Ohio River valleys as well as in Latin America (Cano and Hajjeh, 2001; Kauffman, 2007).

Pathogenesis

In endemic regions, as much as 80% of young adults were previously infected (Edwards *et al.*, 1969). The most common route of infection is through inhalation of conidia followed by conversion to yeast form. The initial host response includes neutrophils, macrophages and dendritic cells. Notably, the fungus can replicate within macrophages travel to other organs via blood or lymph. Infection can be asymptomatic or lead to life-threatening disease. If the host effectively controls the infection, reactivation disease can occur if the cell-mediated immune system is subsequently suppressed or damaged by factors such as HIV, chemotherapy, immunomodulation medications, or cancer (Mihu and Nosanchuk, 2012; Luckett *et al.*, 2014; Woods, 2016).

Endocarditis

Two reviews indicate that *H. capsulatum* accounts for 1%–6% of the fungal endocarditis, behind *Aspergillus* (Ellis *et al.*, 2001; Pierrotti and Baddour, 2002). However, in a review of 21 patients with fungal prosthetic valve endocarditis in an endemic region, 20 patients were immunocompetent and histoplasma accounted for 14% of the cases (Boland *et al.*, 2011). Risk factors for histoplasma endocarditis includes the male sex, rheumatic heart disease and prosthetic valves with complicated perioperative course, but there are also cases involving bicuspid aortic valves, atrial myxoma, and luetic aortic valvulitis. Interestingly, Riddell *et al.*'s case series of 12 patients gathered from 2004 to 2012 described only one patient with HIV and two patients with malignancies. Six patients were in other immunosuppressed states such as congestive heart failure, liver cirrhosis, and chronic kidney diseases (Blair and Raymond, 1981; Riddell *et al.*, 2014).

Across multiple case series, the most consistent clinical symptoms are fever (92–98%), heart murmur (75%–76%), and major artery embolization (19%–32%). Blair described leukopenia (50%) and hepatomegaly or splenomegaly (48%), while Riddell *et al* described heart failure (38%) and splenomegaly (23%). Timing to diagnosis has been consistently prolonged on a scale of weeks to months. Aortic valve involvement was the most common (47%–58%) followed by mitral (19%–31%), and then tricuspid (7%–11%) (Blair and Raymond, 1981; Bhatti *et al.*, 2005; Boland *et al.*, 2011; Riddell *et al.*, 2014).

Diagnosis is usually delayed with negative blood cultures, and the most recent reviews estimating 16%–34% of the patients were serum culture positive and direct tissue cultures were 40%–73% positive. Antigen testing also lack sensitivity as the urine antigen tests was initially positive in 64%, while serum antigen was 50% (Riddell *et al.*, 2014; Bhatti *et al.*, 2005). Morality rate is 13% overall, and for prosthetic valve endocarditis, morality is generally reported as 50%–57% (Boland *et al.*, 2011; Bhatti *et al.*, 2005). However, Riddell *et al.*'s 14-case series included 10 patients with prosthetic valves who had a mortality rate of only 20%.

Myocarditis

There are reports of *H. capsulatum* myocarditis in patients with malignancy or AIDS. Myocarditis can occur by hematogenous dissemination (Merchant *et al.*, 1958). There has been one report of histoplasma myocarditis in an immunocompetent teenager after a mud run with suspected inhalation of heavy inoculum (Scott *et al.*, 2018). Within the tissue, histoplasma granulomas with numerous macrophages filled with yeast cells are usually present, but patients with AIDS may have minimal inflammation or granuloma formation (Binford, 1955; Altieri *et al.*, 1994; Anderson *et al.*, 1988). *H. capsulatum* myocarditis is usually clinically silent; however, sudden cardiac death, heart failure, tamponade, ventricular tachycardia, nonspecific ECG changes and

cardiomegaly can occur (Crawford *et al.*, 1961; Lewis *et al.*, 1985; Scott *et al.*, 2018). Amphotericin and flucytosine is the recommended treatment, and symptoms usually resolve after successful treatment (Kinney *et al.*, 1989).

Blastomyces Dermatitis

Blastomyces dermatitidis is another of the endemic dimorphic fungi in the United States that primarily occurs in areas surrounding the Great Lakes, Mississippi and Ohio River valleys, and around the Saint Lawrence Seaway (Castillo *et al.*, 2016). Within the endemic area, *B. dermatitidis* likely resides in decaying vegetation around surroundings of lakes or other bodies of water (Baumgardner *et al.*, 1992).

Pathogenesis

Most infections are acquired via inhalation of mold forms with subsequent conversion to yeast phase in the lungs (Saccante and Woods, 2010). Once the mold reaches the lung, alveolar macrophages, neutrophils, and monocytes are the main responders (Drutz and Frey, 1985). The conversion to yeast form facilitates immune evasion (Smith and Gauthier, 2015). Blastomycosis typically induces a characteristic pyogranulomatous response. The elimination of the fungi is primarily dependent on the induction of cell-mediated immunity (Wüthrich *et al.*, 2016).

Cardiac infections are an exceedingly rare consequence of disseminated blastomycosis. As of 2013, Alhaji and Sadikot stated that there are only 5 case reports in the known literature with the oldest case reported back in 1914, which described multiple myocardial abscesses (Alhaji and Sadikot, 2013; Hurley, 1916). One case described in 1951 details a patient with primary infection of a lung tumor that progressed to endocarditis with septic thrombi resulting in major arterial occlusions to organs and lower extremities (Pond and Humphreys, 1952). Interestingly, disseminated blastomycosis is quite rare in patients with solid organ and bone marrow transplants when compared to other fungi such as the *Candida* spp., *Aspergillus* spp., and *C. neoformans* (Kauffman *et al.*, 2014). Clinical presentations are non-specific, and they include dyspnea with sputum production, fever, night sweats, tachycardia, leukocytosis. Skin lesions were not readily described in these case reports.

Disseminated blastomycosis is often delayed in its diagnosis due to its low prevalence, but blastomycosis should be considered in patients with pulmonary symptoms and skin involvement, which can increase the specificity to 64% in an endemic area (Chapman *et al.*, 1997). Blood cultures are generally negative. There is an urine antigen detection assay with a positive predictive value of 92.9% in patient blastomycosis, and 89.3% in cases of disseminated disease, but there seem to be strong false positives in patients with histoplasmosis and paracoccidioidomycosis (Saccante and Woods, 2010). Moreover, its utility in cardiac infections has not been established. The optimal treatment approach for cardiac blastomycosis has not been determined, but amphotericin B is recommended for severe, disseminated disease (Chapman *et al.*, 2008). Morality of disseminated blastomycosis with cardiac involvement from the 5 case reports is 100%.

Coccidioides

Coccidioidomycosis is caused by *Coccidioides* species, which are endemic fungi in the southwestern United States and Latin America. Most primary infections are asymptomatic, while symptomatic patients usually present with flu-like symptoms to pneumonia. Extrapulmonary presentation accounts for <1% of the cases (Saubolle *et al.*, 2007).

Pathogenesis

Pathogenesis is not completely understood, but inhalation of arthroconidia of this fungus undergoes morphogenic transition into a spherule, a multinucleated spherical structure. The spherule can subsequently release 800–1000 endospores into the nearby tissue, which then form into new spherules (Saubolle *et al.*, 2007). T cell-mediated immune response plays a crucial role in eradication, but how the response is regulated is largely unknown (Galgiani, 1993). The endospores can disseminate via lymphatics and blood (Saubolle *et al.*, 2007).

Endocarditis

Cardiac involvement may occur with disseminated disease, where the risk factors include the male sex, African or Filipino ancestry, pregnant women in their 2nd and 3rd trimester, and immunosuppression from medication or HIV (Saubolle *et al.*, 2007). Prolonged coccidioidomycosis increases risk for cardiac disease (Reuss *et al.*, 2004). However, cardiac involvement is very rare. Most common symptoms include cough, chest pain, and dyspnea. Infections have occurred on both prosthetic and native aortic or mitral valves. Blood cultures are rarely positive, and serological titers can range from 1:1 to 1:2048 for endocarditis. In contrast to other fungal vegetations that are frequently large and bulky, *Coccidioides* vegetations may be small such that they can be missed by

transesophageal echocardiogram (Chan *et al.*, 2016). The recommended treatment is amphotericin B with surgery, which, in one study, resulted in 4 out of 6 patients surviving (Hornig *et al.*, 2015; Chan *et al.*, 2016).

Myocarditis

From autopsy case series, myocarditis occurs at a rate between 9% to 28% in patients with disseminated coccidioidomycosis. Microscopically, spherules are dispersed within the myocardium, with abscesses characterized by central necrosis but lacks. Granulomas may be present but are frequently absent in individuals with AIDS (Gore and Saphir, 1947; Bloor, 1978; Chapman and Kaplan, 1957; Forbus and Besterbreutje, 1946). Patients with AIDS are at high risk for hematogenous disseminated infection (Minamoto and Rosenberg, 1997). Most cardiac lesions in patients with AIDS are clinically latent or may be masked by respiratory findings (Hofman *et al.*, 1992). Since the literature is largely autopsy reports, there is limited information on clinical symptoms of *Coccidioides* myocarditis. Chapman and Kaplan reported on six patients with cardiac infection that all had dyspnea and orthopnea. Of note, half of these patients also had pericarditis who also had chest pain with EKG showing S-T segment elevation and T wave abnormalities. Pericarditis can occur from myocardial abscesses rupturing into the pericardial space (Chapman and Kaplan, 1957; Chan *et al.*, 2016; Schwartz *et al.*, 1976; Forbus and Besterbreutje, 1946).

Cryptococcus Neoformans

Cryptococcus neoformans is the main causative pathogen of cryptococcosis where it is estimated to cause 80% of cryptococcosis cases worldwide. *Cryptococcus gattii* is responsible for most of the other cases (Heitman *et al.*, 2010). *C. neoformans* has a global distribution, and it is particularly abundant in soil rich in pigeon guano (Emmons, 1951).

Pathogenesis

Infection begins with inhalation of airborne yeast cells or basidiospores. In the lung, alveolar macrophages phagocytose the pathogens and then trigger CD4 + T Helper type 1 dependent immunity, which is crucial for anti-cryptococcal defense (Olszewski *et al.*, 2010). *Cryptococcus* has characteristic polysaccharide capsule that serves as its main source of virulence (Fromtling *et al.*, 1982). This capsule hinders phagocytosis and antibody binding, while promotes intracellular survival within phagosomes. Additionally, capsular component glucuronoxylomannan and galactoxylomannan are anti-inflammatory. Interestingly, the fungus has adapted to increase its capsule size after infecting its host (Granger *et al.*, 1985; Kozel *et al.*, 1977; Kozel, 1993; Alvarez *et al.*, 2008). *C. neoformans* also has a variety of other mechanisms to increase its survival within the host (Olszewski *et al.*, 2010), with melanin being especially important (Nosanchuk *et al.*, 2000; Nosanchuk and Casadevall, 2006). The fungus is also able to remain dormant within granulomas and can reactivate and disseminate in patients with HIV or other immunosuppressive conditions such as corticosteroid treatment. *C. neoformans* primarily presents as meningoencephalitis, but it can involve every organ, although cardiac involvement is rare (Kwon-Chung *et al.*, 2014).

Endocarditis

Cryptococcal endocarditis is a very rare entity. According to Roy *et al.*, there around 10 reported confirmed cases (Banerjee *et al.*, 1997; Boden *et al.*, 1983; Colmers *et al.*, 1967; Lombardo *et al.*, 1957; Alhaji and Sadikot, 2011; Blanc *et al.*, 1996; Harford, 1974; Roy *et al.*, 2018; Nakajima *et al.*, 2019; Kowatari *et al.*, 2019). Comorbidities that predispose these patients include rheumatic heart disease or mitral stenosis, prosthetic aortic or mitral valve, diabetes mellitus, chronic kidney disease, acute lymphocytic leukemia, and substance misuse. Clinical symptoms include dyspnea, weight loss, fever, splenomegaly, hepatomegaly, 1st degree atrial-ventricular block, and thromboembolic events. Diagnosis was delayed in all the cases due to initially negative blood cultures, but the fungus eventually grew in 66% of the cases. Serum cryptococcal antigen was detected in most cases. For treatment, Amphotericin-B is the initial drug and concomitant flucytosine should be considered. Infected prosthetic valves needed replacement, but native valve endocarditis may be treated with medical therapy alone with success. Overall, estimated overall mortality is ~44% (Nakajima *et al.*, 2019).

Myocarditis

Up until 1983, cryptococcal myocarditis was a rare opportunistic infection in patients with immunocompromised conditions such as cirrhosis, malignancies, or steroid use (Bergman *et al.*, 1967; Wilson *et al.*, 1970; Zimmerman and Rappaport, 1954). Since then, cryptococcus myocarditis, although still rare, has been more associated with AIDS. Cryptococcal myocarditis may have abscess, and histologically has yeast cells diffusely infiltrating the myocardium with minimal acute or chronic inflammation. Clinical symptoms are non-specific; although they can include heart failure with ECG abnormalities have been described (Lafont *et al.*, 1987; Nosanchuk, 2002).

Zygomycetes (Phycomycetes)

Zygomycetes is a class of molds where fungi within orders *Mucorales* and *Entomophthorales* are pathogenic (Chayakulkeeree *et al.*, 2006).

According to a review of 929 case reports, genera *Rhizopus* and *Mucor* are two most common culprits of zygomycosis. The male sex, diabetes and malignancy are the biggest risk factors at 65%, 36% and 17%, respectively. Solid organ transplant, bone marrow transplants, and HIV infection have lower associations at 7%, 5%, and 2%, respectively. Zygomycosis mainly involve rhino-orbital-cerebral infection. However, cardiac involvement is a rare but serious complication of disseminated disease, which has mortality approaching 100% (Rodén *et al.*, 2005). Cardiac zygomycosis is thought to be secondary to primary pulmonary disease with angioinvasion, and it can result in pericarditis, myocarditis, myocardial infarction due to fungal thrombus, endocarditis, chordae tendineae rupture, arrhythmias, and congestive heart failure (Tuder, 1985; Jackman and Simonsen, 1992). Standard therapy involves high dose Amphotericin B and aggressive surgery (Riley *et al.*, 2016).

Of the *Entomophthorales*, *Conidiobolus* spp. and *Basidiobolus ranarum* are the most commonly encountered, but they are usually located in tropical regions and are not angioinvasive, so they are not often associated with dissemination or cardiac infections (Ribes *et al.*, 2000). One team reported *Conidiobolus* endocarditis in a cocaine user where the organism demonstrated angioinvasion (Jaffey *et al.*, 1990). A patient with a renal transplant with disseminated *Conidiobolus coronatus* developed a pericardial effusion due to the fungus (Walsh *et al.*, 1994).

Miscellaneous Fungi

The following fungi are extremely rare causes of cardiac infections, with only one or a few case reports to date. These include *Fusarium soleni*, *Trichosporon beigelii*, *Blastoschizomyces capitatus* (Ghosh *et al.*, 2018; Ramos *et al.*, 2004; Polacheck *et al.*, 1992). Disseminated Phaeohyphomycosis can also lead to endocarditis or myocarditis, but this disease describes a group of melanin-pigmented dematiaceous fungi that include *Scedosporium prolificans*, *Myceliophthora thermophila*, *Exophiala jeanselmei*, *Bipolaris spicifera*, and *Bipolaris* species (Nosanchuk, 2002). Cardiac involvement happens in disseminated stage of the disease especially in hosts with prosthetic valves or with immunocompromising conditions with AIDS, malignancy, end-stage renal disease, solid organ or bone marrow transplants.

Fungal Ophthalmological Infections

Daniel J Polla and Joann J Kang, Albert Einstein College of Medicine, Bronx, NY, United States

© 2021 Elsevier Inc. All rights reserved.

Introduction

Tremendous advances in medicine including immunosuppressive agents for organ transplants and autoimmune diseases, new chemotherapies to combat cancer, and the discovery of highly-active antiretroviral therapy to treat HIV/AIDS have saved lives and improved quality of life. With these advances, however, the incidence of observed local and systemic fungal infections has increased. Although fungal infections are significantly less common than bacterial infections of the human eye, there are a variety of fungal infections that ophthalmologists encounter in clinical practice.

Candida, *Fusarium*, and *Aspergillus* are common culprits of fungal keratitis, or infection of the cornea. Another term for fungal keratitis is keratomycosis. These infections occur most commonly following trauma to the eye with exposure to soil, organic, or vegetable matter, but can result from contact lens wear as well. *Candida*, *Aspergillus*, *Cryptococcus*, *Coccidioides*, and *Fusarium* are the most common causes of fungal endophthalmitis, or infection of the intraocular cavities (i.e., aqueous and vitreous humor), and most commonly reach the eye via hematogenous dissemination from a systemic infection. *Histoplasma capsulatum* can cause ocular histoplasmosis syndrome, a multifocal infection affecting the choroid and retina after hematogenous dissemination from inhalation of spores into the lungs. *Cryptococcus neoformans* can cause disease of the brain and optic nerve in an immunocompromised state, resulting in optic neuropathy. Ocular rhinosporidiosis from exposure to *Rhinosporidium seeberi* can present as sessile or pedunculated lesions in the conjunctiva. Exposure to *Blastomyces* and *Sporothrix* can result in focal granulomas or dermatitis affecting the eyelid and/or conjunctiva. Lastly, nonseptate filamentous fungi such as *Mucor* and *Rhizopus* can cause life-threatening infections of the paranasal sinuses, brain, and orbit in immunocompromised patients ([American Academy of Ophthalmology, 2017a](#)).

This chapter will focus on the two most common fungal infections of the eye: fungal keratitis and fungal endophthalmitis. For each infection, its epidemiology, signs and symptoms, diagnostic workup, and treatment will be described.

Fungal Keratitis

Overview

Infectious keratitis, or infection of the cornea from a viral, bacterial, fungal, or parasitic agent, can result in severe visual impairment. When infectious keratitis is associated with a corneal epithelial defect (or opening of the corneal surface), the infection is commonly described as a corneal ulcer. Fungal keratitis is much less common than bacterial keratitis, representing less than 10% of cases in developed countries and roughly 40% of cases in the developing world. The most common cause of fungal keratitis is trauma to the cornea from plant, organic, or vegetable matter. Other risk factors include contact lens wear, topical corticosteroid use, immunocompromised status, previous corneal surgery, chronic keratitis (particularly from herpes simplex virus), and other chronic erosions and/or pathology of the cornea.

Epidemiology and Risk Factors

In the United States, less than 10% of microbial keratitis cases are from fungal infections, although the prevalence is much higher in tropical climates. In southern Florida, fungal keratitis is estimated to be 35% of microbial keratitis cases, compared to 17% in Texas and 1% in New York ([Asbell and Stenson, 1982](#)). Worldwide, this relationship with climate is also evident; a study in Bangkok, Thailand found that 38% of ulcerative keratitis cases were from a fungal etiology, and the most common organism isolated was *Fusarium* species ([Sirikul et al., 2008](#)).

Multiple studies have demonstrated that fungal keratitis is more likely than bacterial keratitis to be associated with ocular trauma, particularly from vegetable, organic, or plant matter. An investigation of fungal keratitis in South India demonstrated that 54.4% of cases were associated with a history of recent trauma to the affected eye. The object causing the trauma was not reported in 37.5% of cases, injury with plant material was reported in 13.9% of cases, injury with animal material was reported in 2.1% of cases, and a history of dust going into the eye was reported in 11.4% of cases. A significant percentage (48.3%) of patients were engaged in outdoor activities for their occupation ([Gopinathan et al., 2002](#)).

Fungal keratitis is also less likely to be associated with contact lens wear than bacterial keratitis. However, in 2006, an outbreak of *Fusarium* keratitis was associated with use of ReNu with MoistureLoc (Bausch & Lomb, Rochester, NY, USA) contact lens solution, which was subsequently removed from the market. A retrospective case series performed during this time period demonstrated that among fungal keratitis cases, 22% of cultures grew yeasts, 72% grew filamentous fungi (of which 54% were *Fusarium* culture positive), 3% grew nonfilamentous fungi, and 3% grew fungi not further identified. Prior to and following this

Fig. 1 Fungal keratitis secondary to *Fusarium*.

outbreak, fungal keratitis has been reported to comprise less than 5% of microbial keratitis cases among contact lens wearers overall (Chang *et al.*, 2006).

Other risk factors for fungal keratitis include systemic and/or topical corticosteroid use, immunocompromised status, previous corneal surgery, chronic keratitis, and chronic pathology of the cornea (American Academy of Ophthalmology, 2017a). Topical and systemic corticosteroids decrease the cornea's immune response and can increase the virulence of fungal organisms. Immunocompromised status can make fungal infection more likely as the body cannot mount an adequate immune response for defense against these organisms. Previous corneal surgery, chronic keratitis, or corneal pathology can lead to irregularities or erosions of the corneal surface, known as the epithelium, disrupting the physical protective barrier that it provides for the eye. This allows virulent organisms to penetrate the deeper corneal layers and infect the cornea.

The most common fungal species associated with fungal keratitis are *Fusarium* Fig. 1, *Aspergillus*, and *Candida*. In the Mycotic Ulcer Treatment Trial, a randomized clinical trial comparing antifungal medications to treat fungal keratitis in South India, microbial culture results demonstrated *Fusarium* growth in 39% of fungal cultures, *Aspergillus* in 16%, and *Curvularia* in 6% (Prajna *et al.*, 2013).

Signs and Symptoms

Symptoms of fungal keratitis include severely decreased visual acuity, foreign body sensation, tearing, discharge, and photophobia. A characteristic finding is eye pain that is severe and out of proportion to the amount of inflammation. On examination, patients with fungal keratitis often exhibit fewer signs of eye inflammation compared to patients with bacterial keratitis (i.e., minimal injection of the conjunctiva). The exam typically demonstrates a corneal infiltrate, or feathery, gray-white opacification of the cornea Fig. 2. The infiltrate may contain filamentous margins and/or multifocal satellite lesions. In severe cases, a plaque may be present along the most posterior layer of the cornea, known as the corneal endothelium, consisting of infectious material and indicating that the infection has progressed through the cornea and may penetrate into the anterior chamber of the eye. A hypopyon, or layering of inflammatory and white blood cells in the anterior chamber of the eye, may be present as well. Significant anterior chamber infection may lead to fungal invasion of the iris, resulting in elevated intraocular pressure. Invasion into the sclera can result in scleritis, which can be complicated by scleral thinning Fig. 3 and/or nodules Fig. 4. Fungal invasion of the posterior chamber of the eye results in fungal endophthalmitis.

Diagnostic Workup

In clinical practice, a patient with suspected fungal keratitis requires a slit lamp examination, which involves the use of an upright microscope to examine the eye by an ophthalmologist. If fungal keratitis is suspected or observed, a culture is collected. To perform this procedure, a swab is scraped against the cornea to collect a sample from the infiltrate. This sample is then placed on agar plates with culture media and sent to a microbiology laboratory for analysis. Multiple culture media for fungi can be utilized, such as Sabouraud dextrose agar and brain heart infusion agar, and fungal hyphae and yeast cells are readily labeled with stains that include Gomori methanamine silver, Calcofluor white, and Periodic acid-Schiff (American Academy of Ophthalmology, 2017a).

In addition to laboratory evaluation, confocal microscopy can be useful to differentiate fungal from bacterial, viral, or parasitic keratitis. Confocal microscopy is an optical imaging technique that can capture multiple, two-dimensional images to create a reconstructed, three-dimensional image. In cases of suspected fungal keratitis, it can provide visualization of branching filaments, individual septa, and other fungal characteristics to aid in prompt diagnosis. Confocal microscopy may be able to differentiate fungal from bacterial keratitis while the clinician awaits culture results from the laboratory.

Fig. 2 A corneal infiltrate secondary to yeast infection. Note the white central opacification of the cornea.

Fig. 3 Severe scleral thinning with visible uveal tissue. This patient developed a fungal keratitis with extension into the sclera secondary to *Aspergillus*.

Fig. 4 Large nodule in *Aspergillus* scleritis. This patient previously received a tectonic penetrating keratoplasty secondary to severe *Aspergillus* keratitis.

Treatment

The initial treatment for fungal keratitis consists of topical antifungal medications. Natamycin 5% suspension is the gold-standard antifungal agent used for filamentous fungal keratitis, including *Fusarium* species. The Mycotic Ulcer Treatment Trial evaluated topical natamycin 5% and topical voriconazole 1% for the treatment of filamentous fungal keratitis, and found that natamycin treatment was associated with significantly better clinical and microbiological outcomes than voriconazole treatment, particularly in *Fusarium* cases (Prajna *et al.*, 2013). Topical amphotericin B (0.15%–0.30%) is the medication of choice in treating yeast keratitis, including *Candida* species, however it serves as an additional option for the treatment of filamentous keratitis caused by *Aspergillus* species.

Oral antifungal agents are frequently used in addition to topical agents to treat more severe cases of fungal keratitis. Among the azoles, ketoconazole, fluconazole, and itraconazole can be utilized. However, oral voriconazole and posaconazole have superior intraocular penetration and are often the preferred oral agents for fungal keratitis (and any fungal eye infection for which oral antifungal agents are considered). However, evidence in the medical literature is lacking to support the use of these oral agents in the treatment of fungal keratitis. The Mycotic Ulcer Treatment Trial II evaluated the use of oral voriconazole in addition to topical agents in the treatment of filamentous fungal keratitis and found no benefit to adding oral voriconazole ([Prajna et al., 2016](#)). The study also showed a significant increase in adverse events in the group that received topical antifungals with oral voriconazole compared to the group that received topical antifungals alone ([Prajna et al., 2016](#)).

In severe cases of fungal keratitis, a corneal transplant may be necessary to preserve corneal integrity or prevent scleral or intraocular extension if the infection progresses on maximal topical and/or oral antifungal therapy. This is known as a tectonic penetrating keratoplasty. If the infection clears solely with medical management, the patient may be left with a visually significant corneal scar. These patients may undergo routine penetrating keratoplasty to improve visual acuity.

Fungal Endophthalmitis

Overview

Endophthalmitis is inflammation of both the anterior and posterior chambers of the eye from bacterial or fungal infection. Endophthalmitis is generally subdivided into two types: exogenous and endogenous. Exogenous endophthalmitis occurs when bacteria or fungi are introduced into the eye from an external source, such as trauma, intraocular surgery, or progressive keratitis. Endogenous endophthalmitis results when bacteria or fungi are hematogenously disseminated into the eye.

Epidemiology

A retrospective study in Miami, Florida published in 2008 evaluated all culture-positive cases of exogenous fungal endophthalmitis over a sixteen year period and found that 44% of cases were associated with fungal keratitis, 24% of cases occurred after penetrating intraocular trauma, and 32% of cases occurred following intraocular surgery. Filamentous fungi accounted for 85% of cases and *Candida* species accounted for 15% of cases ([Wykoff et al., 2008](#)).

Postoperative endophthalmitis can be classified as acute or chronic. Acute postoperative endophthalmitis typically occurs 48–72 hours after surgery, has an incidence between 0.07% and 0.1%, and is most commonly bacterial in etiology. Chronic postoperative endophthalmitis can occur as early as 1–2 weeks after surgery, however can present months and sometimes years later. The incidence of chronic postoperative endophthalmitis is not well-documented in the medical literature due to its insidious nature and delay in diagnosis, however the disease is known to be of both fungal or bacterial etiologies. Common fungal agents that can cause chronic postoperative fungal endophthalmitis include *Candida parapsilosis*, *Aspergillus flavus*, *Candida glabrata*, *Paecilomyces lilacinus*, and *Verticillium* species ([American Academy of Ophthalmology, 2017b](#)).

Risk factors for exogenous endophthalmitis following ocular trauma include retained intraocular foreign body, rural setting of injury, disruption of the crystalline lens during the trauma, and delay in primary wound closure. The incidence of exogenous endophthalmitis (bacterial and fungal) following open-globe injuries is approximately 1%, compared to the rate of 0.1% following intraocular surgery ([Ahmed et al., 2012](#)). Fungal etiologies are less common than bacterial, but injury with vegetable, soil, or organic matter increases the likelihood of fungal infection. Common fungal agents include *Candida*, *Aspergillus*, *Paecilomyces*, *Fusarium*, and *Dematiaceous* species.

Endogenous endophthalmitis typically occurs following fungal infection of the bloodstream in severely immunocompromised individuals, intravenous drug users, those with prior use of indwelling catheters, or long-term antibiotic use. The most common fungal agents implicated in endogenous endophthalmitis include *Candida*, *Aspergillus*, and *Fusarium* ([American Academy of Ophthalmology, 2017b](#)).

Among cases of endogenous endophthalmitis secondary to *Candida* species, a history of recent gastrointestinal surgery, hyperalimentation, diabetes mellitus, and organ transplantation are implicated as risk factors ([Shah et al., 2008](#)). *Candida albicans* is the most common pathogen, although other species such as *Candida parapsilosis*, *Candida tropicalis*, and *Candida glabrata* have also been identified as causative agents ([Krishna et al., 2000](#)).

The incidence of endogenous endophthalmitis is considered rare, however reported incidences vary. Studies in the medical literature report that the incidence of endophthalmitis in patients with a positive fungal blood culture for *Candida* ranges from 0% to 52%; however, in 1994 a classification for ocular candidiasis was published and reported incidences for endophthalmitis subsequently declined. A 2019 systematic review demonstrated that the cumulative incidence rate among studies across years was 2.3% ([Breazzano et al., 2019](#)).

Signs and Symptoms

Symptoms of fungal endophthalmitis include blurred vision, photosensitivity, floaters, and eye pain. In cases following ocular surgery, patients may present with delayed-onset, progressive inflammation that is unresponsive to or even worsens after corticosteroid therapy. Ocular examination may demonstrate decreased visual acuity, periorbital and eyelid edema, conjunctival

injection, corneal haze, anterior chamber cell or inflammation, hypopyon, vitreous haze, retinal hemorrhages, retinal exudates, cotton wool spots, vascular sheathing, and areas of retinal whitening. Ocular involvement is typically unilateral in exogenous endophthalmitis as the etiology is frequently from surgery or trauma. Endogenous endophthalmitis is also typically unilateral, however both eyes can be affected simultaneously.

Diagnostic Workup

Any patient with ocular signs and symptoms concerning for endophthalmitis must seek ophthalmologic evaluation and receive a dilated eye exam. A thorough history is crucial to determine a possible etiology, which will guide subsequent workup.

If trauma has occurred and an intraocular foreign body is suspected, diagnostic imaging may aid in its detection. Axial computed tomography (CT) scans with fine cuts through the orbit of 0.5–1.0 mm are recommended for visualization of a metallic foreign body of 0.5 mm or larger. CT has limited ability to visualize materials such as wood, ceramics, and plastics, thus magnetic resonance imaging (MRI) can be utilized to localize a foreign body not appreciated on CT. However, MRI employs a strong magnetic field that can attract metal, thus a metallic intraocular foreign body must be definitively excluded first ([Ahmed et al., 2012](#)).

If exogenous endophthalmitis is suspected, then aerobic bacterial, anaerobic bacterial, and fungal cultures of the aqueous and vitreous humor must be obtained. An anterior chamber paracentesis is performed to collect an aqueous humor sample and vitreous aspiration is performed to collect a vitreous humor sample; these procedures can be performed in an ophthalmologist's office. If the decision is made to proceed to surgery for both diagnosis and treatment, a pars plana vitrectomy is performed in an operating room to gain access to the vitreous cavity for vitreous aspiration.

Recommended studies from aqueous and/or vitreous samples include Gram stain, Giemsa stain, and polymerase chain reaction (PCR) of suspected fungi. Cultures must be promptly sent off to a microbiology laboratory. Fungal organisms can be slow-growing and insidious in nature, thus cultures should be retained by the laboratory for at least 2 weeks to ensure adequate time for organism growth.

If endophthalmitis is discovered due to ocular symptoms in the absence of recent trauma, surgery, or previous eye infection, the etiology is presumed to be endogenous. The patient's medical history and any active, systemic infections or diseases must be considered. Consultation with an infectious disease specialist is recommended to evaluate for systemic disease and aid in management.

Screening for endogenous endophthalmitis is performed routinely in clinical practice; the Infectious Diseases Society of America recommends that all patients with positive *Candida* blood cultures undergo a dilated ophthalmologic examination, regardless of ocular symptoms or clinical status ([Pappas et al., 2016](#)). These patients are typically monitored closely for the development of endophthalmitis and receive a repeat dilated ophthalmologic examination 2 weeks after the initial examination. However, a recent systematic review found that most patients captured by routine ophthalmologic screening will have no associated ocular findings, and those who do will respond without changing systemic management, thus the potential harm of examination and possible invasive treatment may outweigh the perceived benefit of screening asymptomatic patients ([Breazzano et al., 2019](#)).

Treatment

In cases of exogenous endophthalmitis associated with ocular trauma, prompt evaluation by an ophthalmologist is crucial to ensure that the integrity of the eye is preserved after injury; if trauma results in a full-thickness wound and intraocular contents are exposed, this is an ophthalmologic emergency called a ruptured globe or an open-globe injury. Immediate surgery by an ophthalmologist to restore the integrity of the globe is necessary. If the injury involves soil material, the patient may require tetanus immunization depending on prior vaccination history ([Ahmed et al., 2012](#)).

If fungal exogenous endophthalmitis is suspected, injection of intravitreal antifungals can be performed at the time of vitreous culture. Frequently in clinical practice, both antibiotics and antifungals are injected concurrently if the etiology of the infection is unknown. If pars plana vitrectomy is performed, intravitreal antifungals are injected at the time of surgery. The intravitreal antifungals of choice in the treatment of fungal endophthalmitis are amphotericin for yeast coverage and voriconazole for filamentous fungal coverage. These injections may be supplemented with systemic antifungals, although the role of systemic therapy is not well established or proven.

In cases of endogenous fungal endophthalmitis secondary to *Candida* species, treatment is often successful with systemic medications alone; frequently azole antifungals are used as they can achieve therapeutic intravitreal levels and have broad-spectrum anti-fungal activity. If treatment is ineffective with systemic antibiotics, pars plana vitrectomy with injection of intravitreal antifungals may be effective in de-bulking the pathogen load ([American Academy of Ophthalmology, 2017b](#)).

Candidiasis

Epidemiology

Oropharyngeal candidiasis (OPC) and esophageal candidiasis (EC) are the most common HIV-associated fungal opportunistic infections and are an important cause of morbidity in people living with HIV (Lortholary *et al.*, 2012; Low *et al.*, 2016). The incidence of OPC is ~16%–40% in antiretroviral therapy (ART)-naive patients (Attia *et al.*, 2001; Wolff *et al.*, 2005; Desakorn *et al.*, 2011), and EC is the second most common AIDS-defining illness (Grabar *et al.*, 2008). There is a clear correlation between worsening immunodeficiency and the occurrence of OPC and EC, with a CD4 + cell count of <200 cells/ μ L a risk factor for both (Mönkemüller *et al.*, 2005; Lortholary and Dupont, 2011). Depletion of the IL-17 producing T-helper-17 cells, a subset of the CD4 cell lineage, allows *Candida* to overcome epithelial defenses and is key to the pathogenesis of mucosal candidiasis (Cassone and Cauda, 2012).

Candida albicans is the most common causative pathogen, however there is significant geographical variation in the prevalence of non-*albicans* species (~10%–60%) such as *C. glabrata*, *C. parapsilosis*, *C. tropicalis* and *C. krusei* (Mushi *et al.*, 2017; Patil *et al.*, 2018). The widespread introduction of ART has significantly lowered the incidence of OPC and EC (Schwartz *et al.*, 2013; Low *et al.*, 2016). However, mucocutaneous candidiasis remains an important cause of morbidity due to lack of access to healthcare services, increasing prevalence of azole-resistant *Candida* species, and in people on ART with poor CD4 + T cell recovery (Patil *et al.*, 2018).

The impact of HIV on vulvovaginal candidiasis (VVC) is uncertain; some studies suggest a higher incidence, while others suggest higher rates of colonization without vaginitis only (Duerr *et al.*, 1997; Ohmit *et al.*, 2003). Multiple other risk factors contribute (antibiotic use, diabetes, vaginal dysbiosis and pH) and VVC is common in women without HIV. Furthermore, HIV is not a risk factor for invasive candidiasis (Kullberg and Arendrup, 2015; Pappas *et al.*, 2018), so this chapter will focus on OPC and EC in HIV.

Clinical Presentation

OPC has different clinical forms. Pseudomembranous candidiasis appears as creamy-white plaques which can be removed with a swab to reveal erythematous or bleeding mucosa, whereas in hyperplastic candidiasis there are homogenous adherent or nodular lesions (Akpan and Morgan, 2002; Patil *et al.*, 2015). In erythematous candidiasis, there are localized patches of erythema, often on the dorsum of the tongue or palate (Akpan and Morgan, 2002) and angular cheilitis appears as fissuring at the corners of the mouth. The pseudomembranous and erythematous variants are the most common in people living with HIV. OPC is often asymptomatic, but may present with pain (particularly with erythematous candidiasis or angular cheilitis) or taste disturbance (Darouiche, 1998).

EC often presents with odynophagia, dysphagia, and/or retrosternal pain (Darouiche, 1998). While concurrent oropharyngeal lesions are common, EC can occur in isolation (Darouiche, 1998; Vazquez, 2010). Symptoms may result in reduced oral intake and weight loss. Important differential diagnoses include other infectious causes of esophagitis (e.g., cytomegalovirus, herpes simplex virus), gastroesophageal reflux disease, strictures, esophageal carcinoma and Kaposi's sarcoma.

Diagnosis

OPC is a clinical diagnosis, based on the appearance of oral lesions. A swab for fungal culture should be performed in those who fail to respond to initial therapy or have recurrent episodes to assess for azole resistance. In patients with oropharyngeal lesions and symptoms of EC, a diagnostic trial of antifungal therapy is appropriate before investigation with endoscopy (Lortholary *et al.*, 2012; Pappas *et al.*, 2015; Dockrell *et al.*, 2019). Endoscopy should be performed in patients with lack of clinical response, those without oropharyngeal lesions, or to exclude an alternative diagnosis (Dockrell *et al.*, 2019). The diagnosis can be confirmed by endoscopic visualization of lesions, alongside tissue biopsies demonstrating microbiological and histopathological evidence of candidiasis.

Management

Prophylaxis

ART initiation is key to preventing OPC and EC and reducing relapses through immune restoration. Primary prophylaxis with fluconazole has been shown to be effective (particularly when CD4 count < 50 cells/uL) (Powderly *et al.*, 1995; Schuman *et al.*, 1997; Lortholary *et al.*, 2012) but is not recommended as it propels resistance emergence (Fichtenbaum *et al.*, 2000). Secondary prophylaxis to prevent relapses is also generally not recommended. For multiple relapses, daily or weekly therapy reduces relapse frequency without increasing the risk of developing fluconazole-refractory disease, compared to episodic fluconazole therapy administered for each relapse (Goldman *et al.*, 2005). Concomitant risk factors and predisposing co-morbidities (inhaled corticosteroids, dentures, oral hygiene, diabetes) should also be optimized.

Treatment

Fluconazole is the recommended first-line therapy for both OPC and EC in HIV patients given its efficacy, availability and low cost (Lortholary *et al.*, 2012; Pappas *et al.*, 2015; Dockrell *et al.*, 2019). It has excellent oral bioavailability and good penetration into gastric tissue and saliva (DeMuria *et al.*, 1993; Felton *et al.*, 2014). Fluconazole 100–200 mg/day for 7–14 days is recommended treatment of OPC, and 200–400 mg/day for 14–21 days in EC (Lortholary *et al.*, 2012; Pappas *et al.*, 2015; Dockrell *et al.*, 2019); the higher dose and duration is indicated for severe or relapsed disease. Fluconazole can be administered orally (tablet or liquid formulation) or parenterally in patients with odynophagia or dysphagia. Studies examining the efficacy of fluconazole have reported clinical cure rates of ~85%–90% of HIV patients with OPC (Pons *et al.*, 1993, 1997; Sangeorzan *et al.*, 1994; Flynn *et al.*, 1995) and EC (Phillips *et al.*, 1998; Villanueva *et al.*, 2002).

For milder cases of OPC, topical therapies such as nystatin (100,000 units/mL, 5 mL four times daily for 7–14 days), clotrimazole trouches (10 mg trouches, five times per day 7–14 days) or miconazole buccal adhesive tablets may be considered (Pons *et al.*, 1993; Flynn *et al.*, 1995; Vazquez *et al.*, 2010). Nystatin and clotrimazole are less efficacious, with higher rates of relapse when compared to fluconazole (Pons *et al.*, 1993, 1997; Powderly *et al.*, 1995).

Refractory OPC or EC is defined as persistent symptoms despite ≥ 14 days of ≥ 200 mg/day of fluconazole (Lortholary *et al.*, 2012). Prior azole exposure and persistent immunodeficiency (particularly CD4 count < 50 cells/ μ L) are risk factors. In such cases, *Candida* speciation and susceptibility testing are advised to tailor further therapy. While cross resistance to triazoles can occur, itraconazole is effective in 55%–65% of fluconazole-resistant cases (Phillips *et al.*, 1996; Saag *et al.*, 1999), and posaconazole in 74% of itraconazole- and fluconazole-resistant isolates (Skjest *et al.*, 2007). Itraconazole oral solution has better bioavailability than capsules, with similar clinical and mycological cure rates as oral fluconazole (Wilcox *et al.*, 1997; Phillips *et al.*, 1998). Echinocandins have a similar efficacy to fluconazole, but higher rates of relapse and can only be administered intravenously (Villanueva *et al.*, 2002; Krause *et al.*, 2004). Hence, echinocandins should be reserved for use in pan-azole resistant cases or where there is a contraindication to azole administration. Amphotericin B deoxycholate (0.5 mg/kg/day) is less well tolerated compared to echinocandin therapy (Villanueva *et al.*, 2001; Arathoon *et al.*, 2002) and should be reserved for use when there are no suitable alternatives. With all therapies, but particularly the triazoles which are potent CYP450 enzyme inhibitors, it is crucial to consider drug-drug interactions prior to prescribing.

Cryptococcosis

Epidemiology

Cryptococcosis is the most common AIDS-related opportunistic mycosis globally, with an estimated 223,000 infections occurring each year causing 180,000 deaths, accounting for 15% of AIDS-related deaths (Rajasingham *et al.*, 2017). Exposure to the causative pathogens, the ubiquitous environmental saprophytes *Cryptococcus neoformans* or *Cryptococcus gattii*, is via inhalation (Perfect and Casadevall, 2002; May *et al.*, 2016). In the context of advanced HIV infection with depressed CD4 T-cell count (< 100 cells/ μ L), dissemination from the lungs occurs either following acute exposure or reactivation of latent infection, spreading hematogenously to most organs, with a predilection for the central nervous system resulting in cryptococcal meningoencephalitis (CM) (Mitchell and Perfect, 1995; Williamson *et al.*, 2016).

Disease burden is greatest in sub-Saharan Africa (Rajasingham *et al.*, 2017) where despite excellent ART coverage, CM incidence remains high (Osler *et al.*, 2018; Tenforde *et al.*, 2019) and access to the best antifungal drugs is lacking (Loyse *et al.*, 2013). In the HIV-infected patient, CM can present as an AIDS-defining opportunistic infection in the ART-naïve patient, as unmasking of latent infection through immune restoration within the first few months of starting ART, or as a manifestation of defaulted or failed ART, with the latter now responsible for > 50% of CM presenting in sub-Saharan Africa (Molloy *et al.*, 2018; Osler *et al.*, 2018; Rhein *et al.*, 2018).

Clinical Presentation

CM usually presents sub-acutely, presenting most commonly as headache, sometimes accompanied by confusion, drowsiness, seizures, visual or hearing loss. In advanced HIV, clinical signs may be absent but can include reduced conscious level, meningism,

Fig. 1 Cutaneous lesions associated with disseminated mycoses in HIV/AIDS. A. Ulcerated nodules in South African female with unmasking disseminated cryptococcosis (serum CRAG >1:2048) characterized as diarrhea, weight loss and shortness of breath developing one month after commencing ART. B. Gram stain of aspirate from facial lesion in A. revealed budding yeasts (*C. neoformans*). C. Progressive disseminated histoplasmosis in Colombian male with multiple facial papules, some showing ulceration Disseminated talaromycosis in a Vietnamese male presenting with 1 month of fever, fatigue, and diarrhea and 4 days of characteristic central-necrotic skin lesions skin lesions that began on the face and spread to his trunk and extremities.

papilledema and cranial nerve palsies – most commonly VI nerve palsy secondary to raised intracranial pressure (CSF opening pressure > 20 cm), (Graybill *et al.*, 2000; Bicanic *et al.*, 2009; Rolfes *et al.*, 2014). Altered mental status and elevated baseline CSF fungal burden (cryptococcal antigen/CRAG titers > 1024 or quantitative cryptococcal culture) are adverse prognostic markers (Saag *et al.*, 1992; Jarvis *et al.*, 2014). Cryptococcomas can occur following immune restoration through ART, presenting as focal neurological signs (Haddow *et al.*, 2010).

Pulmonary cryptococcosis can have myriad manifestations from asymptomatic to cough and dyspnea with focal or diffuse pulmonary infiltrates, which can be misdiagnosed as pulmonary tuberculosis (Jarvis and Harrison, 2008). Other common manifestations in HIV-infected patients include skin lesions (a manifestation of disseminated disease)- most frequently papules with a soft or ulcerated center (Fig. 1(A)). Other infection sites include bone and lymph nodes (Mitchell and Perfect, 1995).

Diagnosis

A lumbar puncture (LP) is the investigation of choice in HIV-infected patients presenting with a CD4 count <100 cells/ μ L and headache. Typical CSF findings include lymphocytosis (can be absent in advanced HIV), mildly elevated protein (0.5–1 g/dL) and low CSF glucose. The India ink test, showing the characteristic yeasts with a surrounding halo, is a simple and cheap test which is 70%–90% sensitive in patients with HIV/AIDS (Bicanic and Harrison, 2004), who have higher fungal burdens compared to

immunocompetent patients. The detection of capsular polysaccharide antigen (CRAG) in CSF or serum is >95% sensitive and specific for diagnosis of CM (WHO, 2019). CRAG titers correlate with CSF fungal burden by quantitative culture: although titers fall with successful treatment, the kinetics of the decline are very slow and cannot be used to monitor response to therapy nor in deciding when to stop maintenance therapy (Brouwer *et al.*, 2005; Perfect *et al.*, 2010).

A cheap CRAG lateral flow device is now widely available at \$2/ test (sub-Saharan Africa) and greatly facilitates diagnosis, including of early dissemination via a serum CRAG (Jarvis *et al.*, 2009; Lindsley *et al.*, 2011). The pooled prevalence of cryptococcal antigenemia is 6.5% in patients with advanced HIV and CD4 count <100 cells/ μ L (Ford *et al.*, 2018). A serum CRAG titer >1:160 is predictive of CNS infection and mandates an LP even in asymptomatic patients (Wake *et al.*, 2018). Blood cultures may be positive in patients with disseminated infection, including those presenting with CM. Cryptococci can also be visualized in skin or lymph node biopsies using specialized fungal stains such as GMS, PAS or mucicarmine (capsule stain) (Bicanic and Harrison, 2004).

Primary antifungal resistance to amphotericin B, fluconazole and flucytosine is rarely observed in global isolate collections (Pfaller *et al.*, 2005), however *Cryptococcus* has an intrinsic heteroresistance to fluconazole which will be missed by conventional MIC testing (Sionov *et al.*, 2009), but will be selected for and predominate upon exposure to fluconazole, resulting in relapse with secondary resistance (Stone *et al.*, 2019). Fluconazole MIC testing is recommended for patients with a culture-positive relapse during the consolidation or maintenance phase of treatment (Govender *et al.*, 2019).

Management

Drug therapy

Antifungal therapy for CM in HIV/AIDS is some of the best studied for invasive mycoses, with evidence from phase II/ III trials incorporating both fungal clearance and mortality supporting a 1–2-week induction regimen using Amphotericin B deoxycholate (AmBd, 1.0 mg/kg/day) plus flucytosine (5FC, 100 mg/kg/day) as the gold standard for HIV-CM (Van Der Horst *et al.*, 1997; Brouwer *et al.*, 2004; Day *et al.*, 2013; Molloy *et al.*, 2018), followed by consolidation with 8 weeks' fluconazole at 400–800 mg/d, then maintenance therapy with 200 mg until immune restoration with ART to CD4 count >100 cells/ μ L and a fully suppressed HIV viral load (Perfect *et al.*, 2010; WHO, 2019).

For settings where intravenous AmBd is unavailable or cannot be safely administered, an all-oral regimen of fluconazole plus 5FC was non-inferior to AmB-based regimens in a recent large African randomised trial, ACTA (Molloy *et al.*, 2018), as well as cost effective compared to fluconazole monotherapy (Shiri *et al.*, 2020). Liposomal amphotericin B (L-AmB) is less toxic compared to AmBd but far more expensive: at 3–6 mg/kg/d for 2 weeks, outcomes were no better compared to AmBd based regimens (Hamill *et al.*, 2010). L-AmB pharmacokinetics facilitate higher intermittent dosing – a single dose of 10 mg/kg on a backbone of 2 weeks' fluconazole plus 5FC is being compared to the standard 2-week induction regimen in the AmBition African phase III trial, with results expected in 2021 (Lawrence *et al.*, 2018; Jarvis *et al.*, 2019). In terms of adjunctive immunotherapy in HIV-CM, dexamethasone was associated with worse fungal clearance and outcome in a phase III trial (Beardsley *et al.*, 2016), whilst IFN- γ enhanced fungal clearance in two phase II trials (Jarvis *et al.*, 2012). 10-week mortality with the optimized antifungal induction regimen in clinical trial settings is 20%–40% (Day *et al.*, 2013; Molloy *et al.*, 2018; Boulware *et al.*, 2020). In the real-world setting in sub-Saharan Africa, where fluconazole monotherapy is marred by poorer fungal clearance and clinical failure due to treatment-emergent resistance (Hope *et al.*, 2019; Stone *et al.*, 2019), this figure approaches 50%–70% (Longley *et al.*, 2008; Rothe *et al.*, 2013; Gaskell *et al.*, 2014). Several novel antifungals with anti-cryptococcal activity are in the pipeline, whilst repurposed agents sertraline and tamoxifen have been disappointing (Beardsley *et al.*, 2016; Boulware *et al.*, 2020).

Raised intracranial pressure (ICP)

Raised ICP must be managed aggressively by CSF drainage through serial lumbar punctures, shown to mitigate its impact on mortality (Rolfes *et al.*, 2014). Temporary drains can be inserted for refractory ICP in CM (Macswen *et al.*, 2005). Almost half of HIV-CM survivors suffer neurological sequelae, including cognitive impairment, visual or hearing loss (Goldberg *et al.*, 2018).

Cryptococcal antigen screening

To prevent CM in advanced HIV, the WHO recommends a serum CRAG-based screening strategy for Persons living with HIV (PLHIV) with CD4 counts <100 cells/ mm^3 , and fluconazole pre-emptive treatment in those testing positive, until immune reconstitution (WHO, 2019). Even with this approach, CRAG-positive patients suffer excess 6-month mortality compared to CRAG negatives (Mfinanga *et al.*, 2015; Wake *et al.*, 2020): ongoing trials (ACACIA NCT03945448; EFFECT) are exploring addition of either L-AmB or flucytosine to fluconazole to treat cryptococcal antigenemia.

Immune restoration and ART timing

Immune restoration through ART is essential for all ART-naïve patients with AIDS-related mycoses: if ART has not already started, initiating ART after 4–6 weeks of optimal antifungal therapy is recommended in CM (Boulware *et al.*, 2014). IRIS (immune response inflammatory syndrome) can occur either as unmasking (CSF culture positive) or paradoxical (CSF usually culture negative) (Haddow *et al.*, 2010): the latter occurs in 10%–30% of CM patients, usually in the early months following start of ART: CSF cultures are usually sterile, and management includes control of raised ICP and short-course steroids.

Histoplasmosis

Epidemiology

Histoplasmosis, caused by the dimorphic fungus *Histoplasma capsulatum*, is the most frequent cause of fungal respiratory infection and has a broad spectrum of clinical manifestations ranging from a self-limited, acute, influenza-like illness to life-threatening progressive disseminated infection (Deepe, 2020; Thompson and Gómez, 2019). Histoplasmosis is highly endemic in regions of North America, Central America, and South America, as well as being reported in parts of Asia and Africa (World Health Organization/Pan American Health Organization, 2020; Nacher *et al.*, 2016; Bahr *et al.*, 2015). The risk of histoplasmosis is greatest in those with CD4⁺ counts of <200 cells/μL. Despite advances in the treatment of HIV infection, incidence and mortality associated with *H. capsulatum* infection remains high: with an estimated 15,600 new cases and 4500 deaths in the Americas each year (Adenis *et al.*, 2018), where it is estimated to be responsible for 5%–15% of AIDS-related deaths (World Health Organization/Pan American Health Organization, 2020).

The environmental niche for *H. capsulatum* is soil enriched in nitrogen contained in bird and bat guano. Infection begins when small mycelial fragments and microconidia of *H. capsulatum* are inhaled into the alveoli, following which they bind to the CD11-CD18 family of integrins and are engulfed by neutrophils and macrophages (Newman, 1999). After transformation of conidia into yeasts in the lungs, yeasts migrate to local draining lymph nodes and subsequently to distant organs rich in mononuclear phagocytes (e.g., liver, spleen).

The extent of disease is determined both by the number of conidia inhaled and the immune response of the host. Although all primary infections can be considered disseminated because yeast cells migrate from the lungs to organs rich in mononuclear phagocytes, the term progressive disseminated histoplasmosis (PDH) refers to the relentless growth of the organism in multiple organ systems (Deepe, 2020; Thompson and Gómez, 2019). Following exposure, histoplasmosis has been reported to reactivate and cause disease following later immunocompromise, often many years after leaving an endemic area (Miceli *et al.*, 2016).

Clinical Presentation

PDH is the most frequent clinical presentation of histoplasmosis in HIV/AIDS. Symptoms of PDH are non-specific and may be indistinguishable from those of other infectious diseases, especially tuberculosis, complicating diagnosis and treatment (Deepe, 2020; World Health Organization/Pan American Health Organization, 2020; Adenis *et al.*, 2014). Common clinical findings, reported in >90% of patients with AIDS and PDH, include fever, fatigue, weight loss, and respiratory symptoms (Hage *et al.*, 2015; Deepe, 2020). The most common sites of extrapulmonary dissemination are the liver, spleen, gastrointestinal tract and bone marrow (Hage *et al.*, 2015). In severe PDH in HIV-infected patients, defined as the presence of symptoms/ signs involving >1 vital organ and functional impairment (WHO performance status score >2) (World Health Organization/Pan American Health Organization, 2020), gastro-intestinal manifestations were most common (84%), followed by pulmonary manifestations (76%), lymphadenopathy (58%) and skin lesions (49%) (Caceres *et al.*, 2016) (Fig. 1(C)). Laboratory findings include abnormal liver enzyme values and pancytopenia (Deepe, 2020; Caceres *et al.*, 2016). Up to 20% of patients with PDH in one case series were reported to have central nervous system (CNS) involvement (Wheat *et al.*, 1990a,b).

Diagnosis

Culture of *H. capsulatum* is highly specific and remains the gold standard diagnostic test for histoplasmosis, but takes several weeks. Studies show variable sensitivity when cultures are not properly processed (e.g. when blood cultures are not processed by lysis centrifugation), with overall sensitivity of 77% (range 60%–90%) from blood cultures in HIV patients, with much poorer performance from respiratory sample cultures (0%–60%) (Caceres *et al.*, 2019). Where available, histopathological examination of involved tissues reveals distinctive 2–4 μm, oval yeasts with a single narrow-based bud (Deepe, 2020; Thompson and Gómez, 2019; Miceli *et al.*, 2016). Other diagnostic methods include detection of specific host antibodies against *Histoplasma* antigens, detection of circulating *Histoplasma* antigens and detection of fungal DNA.

Antibody tests have high specificity, but low sensitivity (38%–70%) in HIV, likely due to the degree of immunosuppression (World Health Organization/Pan American Health Organization, 2020; Caceres *et al.*, 2019; Hage *et al.*, 2015). Antigen detection assays are the diagnostic modality of choice for PDH in HIV, with overall sensitivity of 95% and specificity of 97% (Connolly *et al.*, 2007; Cáceres *et al.*, 2018; Caceres *et al.*, 2019; World Health Organization/Pan American Health Organization, 2020). Histoplasma antigen levels in urine and serum typically decrease after initiation of antifungal therapy, so serial antigen tests are useful to monitor response to therapy (Hage *et al.*, 2011; Caceres *et al.*, 2014). Antigen detection kits have recently become commercially available (World Health Organization/Pan American Health Organization, 2020; Cáceres *et al.*, 2018), facilitating implementation in clinical laboratories and reducing technical issues related to reproducibility and quality control. Settings implementing *Histoplasma* antigen testing have seen a significant increase in the number of diagnosed cases (Samayoa *et al.*, 2017; Caceres *et al.*, 2015; Bansal *et al.*, 2019; Falci *et al.*, 2019). The recent development of a histoplasma antigen lateral flow assay holds promise of a simple and reliable testing platform (sensitivity 96%, specificity 90%) (Cáceres *et al.*, 2020), but it is not yet commercially available.

PCR-based assays have reported sensitivity of 95% and specificity of 99% (Caceres *et al.*, 2019), but the lack of methodological consensus and unavailability of commercial kits means these assays are not yet in widespread clinical use (World Health Organization/Pan American Health Organization, 2020; Thompson and Gómez, 2019).

Treatment

Amphotericin B deoxycholate has long been the recommended induction therapy of histoplasmosis (Wheat *et al.*, 1990a,b) but is associated with considerable toxicities, including infusion reactions, renal failure, electrolyte abnormalities, and anemia (Johnson *et al.*, 2002; Wheat *et al.*, 2007). A single small randomized trial ($n = 80$) comparing the efficacy of amphotericin B preparations for induction therapy for moderately severe to severe disseminated histoplasmosis among people living with HIV was suggestive of higher clinical success rate and lower risk of death and nephrotoxicity with the liposomal compared to the deoxycholate preparation (Johnson *et al.*, 2002). To date, no randomized trials have compared amphotericin B formulations with triazole antifungal agents for treatment of PDH.

For treatment of severe or moderately severe histoplasmosis in HIV-infected patients, guidelines recommend liposomal amphotericin B (L-AmB) at 3 mg/kg/d for two weeks, with higher doses and duration (3–5 mg/kg/day for 4–6 weeks) used for those with meningitis. In settings where L-AmB is not available, Amphotericin B deoxycholate (AmBd) 0.7–1.0 mg/kg/d is recommended, with measures to prevent and monitor toxicity (Deepe, 2020; World Health Organization/Pan American Health Organization, 2020). Following symptom resolution, therapy is stepped down to itraconazole (200 mg three times daily for 3 days, then 200 mg twice daily) for a total duration of 12 months and/or until clinically stable with immune restoration and HIV viral load suppression on ART (Deepe, 2020; World Health Organization/Pan American Health Organization, 2020). Mild-to-moderate histoplasmosis in HIV can be treated with itraconazole alone for 12 months (Deepe, 2020; World Health Organization/Pan American Health Organization, 2020), with amphotericin B for those failing to improve on or intolerant of azole therapy.

ART should be initiated as soon as possible in HIV-infected patients with disseminated histoplasmosis without CNS involvement (World Health Organization/Pan American Health Organization, 2020); drug-drug interactions are common with triazoles and ART, specifically protease inhibitors and NNRTIs (discussed below). Immune reconstitution inflammatory syndrome (IRIS) associated with histoplasmosis is unusual, occurring at about 0.74 cases per 1000 person-years (Melzani *et al.*, 2020). The features of histoplasmosis-associated IRIS are non-specific and resemble disseminated histoplasmosis. Typically, antifungal therapy does not need to be adjusted. Short-course oral steroid therapy can be considered if there are life-threatening complications (1–2 mg/kg per day of prednisone or equivalent for 1–2 weeks followed by dose-tapering for two weeks) (World Health Organization/Pan American Health Organization, 2020).

Pneumocystis Pneumonia (PCP)

Epidemiology

The dominant opportunistic infection at the beginning of the AIDS epidemic, HIV-associated PCP incidence has declined dramatically in high resource countries over the past three decades due to the introduction of potent combination ART and effective chemoprophylaxis (Maini *et al.*, 2013; Buchacz *et al.*, 2016; Kelley *et al.*, 2009). Despite this decline, PCP remains an important AIDS-defining event (Buchacz *et al.*, 2016), particularly amongst people unaware of their HIV infection or not on ART. Overall mortality of HIV-associated PCP is consistently 10%–13% (Walzer *et al.*, 2008; Schmidt *et al.*, 2018; Roembke *et al.*, 2014), even in cohorts after the widespread introduction of ART (Walzer *et al.*, 2008). Survival is much lower amongst patients with respiratory failure, usually below 70% (Curtis *et al.*, 2000; Fei *et al.*, 2009; Monnet *et al.*, 2008), and outcomes are particularly poor if mechanical ventilation is required. PCP is increasingly recognized as an important cause of pneumonia amongst HIV-infected people in resource-limited countries (de Armas Rodriguez *et al.*, 2011). A recent systematic review found a PCP prevalence over 20% amongst HIV-infected inpatients presenting with respiratory symptoms in sub-Saharan Africa (Wasserman *et al.*, 2016). Outcomes are poor in these settings, with case fatality rates of 15%–30% (Wasserman *et al.*, 2016), reaching 60% in those admitted to intensive care at one center (Chiliza *et al.*, 2018).

Pathophysiology and Clinical Presentation

Absolute and functional CD4 + T cell depletion in HIV-infection results in uncontrolled organism replication and high fungal burden, triggering immune responses that lead to lung damage and characterize PCP pathophysiology. Incidence of HIV-associated PCP is inversely related to CD4 count and most cases occur at CD4 counts below 200 cells/ μ L (Hoover *et al.*, 1993; Stansell *et al.*, 1997). The typical clinical presentation is a sub-acute respiratory illness with progressive dyspnea, cough (which may be productive), and fever (Thomas and Limper, 2004). Constitutional symptoms including weight loss and sweats may also be present (Chiliza *et al.*, 2018). Although onset of respiratory symptoms is usually gradual, over 2–3 weeks, a subset of patients can present with rapidly progressive symptoms over days (Chiliza *et al.*, 2018). Unmasking (ART-associated) or paradoxical immune reconstitution inflammatory syndrome (IRIS) is well-described in HIV-associated PCP, presenting similarly to *de novo* infection (Barry *et al.*, 2002; Koval *et al.*, 2002; Wislez *et al.*, 2001).

Fig. 2 Radiographic features of HIV-associated PCP. 36-year-old man, presented with progressive respiratory symptoms and newly diagnosed with HIV, CD4 cell count 41 cells/mm³. He was unable to produce sputum and *P. jirovecii* testing was not performed. Chest X-ray showed bilateral interstitial and ground glass opacification on presentation (A), becoming more confluent after 5 days (B) along with worsening hypoxia despite high dose cotrimoxazole and corticosteroids. Therapy was switched to clindamycin and primaquine after 2 weeks due to persistent respiratory failure and extensive alveolar-interstitial infiltrates on chest x-ray suggestive of acute respiratory distress syndrome (C). Hypoxia persisted a month after presentation with residual bilateral ground-glass opacification and cyst formation (D).

Exercise-induced oxygen desaturation on pulse oximetry occurs in >90% of PCP cases (Smith *et al.*, 1988, 1992; Stover *et al.*, 1989), and together with compatible clinical presentation and radiology is strongly supportive of the diagnosis. Serum LDH, reflecting lung injury (Quist and Hill, 1995), is elevated in most confirmed PCP cases and has been associated with worse outcome (Chiliza *et al.*, 2018; Zaman and White, 1988; Benson *et al.*, 1991) but does not distinguish PCP from other severe opportunistic infections, including disseminated TB (Butt *et al.*, 2002). Other non-specific inflammatory markers, such as C-reactive protein and procalcitonin, also have poor discriminatory value (Mendelson *et al.*, 2018). In contrast, serum beta-1,3-D-glucan is frequently elevated (Sax *et al.*, 2011) and is a useful diagnostic biomarker for HIV-associated PCP.

Chest X-ray typically shows diffuse bilateral interstitial infiltrates, usually with both central and peripheral distribution, becoming confluent with disease progression (Fig. 2). Unilateral involvement occurs infrequently (DeLorenzo *et al.*, 1987). High resolution computed tomography (HRCT) can detect subtle ground-glass opacification missed on plain radiography, and although non-specific, has high sensitivity and negative predictive value for HIV-associated PCP (Hidalgo *et al.*, 2003).

Diagnosis

Bronchoscopy with BAL is the gold standard diagnostic test but is not widely available in high HIV burden areas and is rarely used in the routine management of patients with suspected PCP in these settings. Immunofluorescent or histochemical staining will identify *P. jirovecii* on induced sputum. In a meta-analysis including 322 HIV-infected patients, the sensitivity and specificity of induced sputum *Pneumocystis* immunofluorescence was 67% and 96% respectively compared to BAL as the reference test. Polymerase chain reaction (PCR) has excellent diagnostic performance in BAL fluid (Fan *et al.*, 2013) and is a good rule-out test on induced sputum (NPV 96%) (Moodley *et al.*, 2017) and even oral wash samples (NPV 91%) (Helweg-Larsen *et al.*, 1998). However, performance varies between sample type, molecular target, and PCR method. The World Health Organization definition

of probable PCP incorporates clinical and radiological features only which are non-specific, especially in the context of COVID-19 (World Health Organization, 2007). A research priority is to derive and validate PCP prediction algorithms, especially in low resource populations with high burden of tuberculosis.

Management

Antimicrobial therapy

Trimethoprim-sulfamethoxazole (TMP-SMX) is the preferred first-line treatment for HIV-associated PCP, regardless of severity. Dosing and duration of therapy is the same as for HIV-negative disease (TMP-SMX 80/400 mg (single strength) 12–16 tabs/day for 21 days), followed by secondary prophylaxis with TMP-SMX two single strength tablets daily until CD4 count >200 cells/μL. Treatment failure on TMP-SMX occurs in approximately 10%; the most frequent cause is TMP-SMX toxicity (predominantly rash and hepatitis), but a subgroup of patients experience progressive disease despite tolerating TMP-SMX (Benfield *et al.*, 2008; Helweg-Larsen *et al.*, 2009). Clindamycin-primaquine is superior to other agents when used as second-line therapy after failing TMP-SMX (Smego *et al.*, 2001; Benfield *et al.*, 2008). Alternative agents for mild disease include trimethoprim-dapsone (Safrin *et al.*, 1996) or atovaquone (for patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency) (Falloon *et al.*, 1991). Intravenous pentamidine is poorly tolerated and associated with increased mortality (Helweg-Larsen *et al.*, 1999). There is interest in adjunctive echinocandin therapy based on promising data from animal models (Cushion *et al.*, 2010; Lobo *et al.*, 2013) but currently insufficient evidence exists to recommend routine use.

Adjunctive therapy

Corticosteroids provide consistent survival benefit (44% relative reduction in mortality) and reduction in mechanical ventilation (60% lower rates) for patients with HIV-associated PCP and respiratory failure (Ewald *et al.*, 2015). International guidelines recommend early initiation of prednisone (or equivalent) for all cases with severe PCP or associated hypoxia (paO₂ <70 mmHg (9.3 kPa)). Optimal dose and duration are unknown, but the standard regimen is prednisone 40 mg 12-hourly for 5 days, followed by 40 mg daily for 5 days and 20 mg daily for 11 days. Tapering can be delayed in very severe or unresponsive disease, or when IRIS is suspected.

Antiretroviral therapy

ART initiation within 2 weeks of PCP diagnosis reduced risk of death and was not associated with increased toxicity or IRIS in a randomized controlled trial (Zolopa *et al.*, 2009). All patients with PCP should be initiated on standard ART as soon as tolerating oral anti-pneumocystis treatment. Clinical-radiological deterioration after starting ART should prompt evaluation to exclude other causes before attributing to paradoxical IRIS.

Ventilatory support

Patients with respiratory failure who are awake and able to maintain their airway benefit from continuous positive airway pressure (CPAP) by face mask (Gregg *et al.*, 1990). Intubation and mechanical ventilation is reserved for patients that do not improve on CPAP (Boix *et al.*, 1995), and should be delivered with low tidal volumes and plateau pressures (Davis *et al.*, 2008). Extracorporeal membrane oxygenation (ECMO) has been used successfully for refractory ARDS (Ali *et al.*, 2016; Cawcutt *et al.*, 2014).

Emergomycosis

Epidemiology

Emergomycosis is a severe multisystem HIV-associated mycosis caused by a novel thermally dimorphic fungus, *Emergomyces* sp. Initially described as an *Emmonsia*-like fungus among patients with advanced HIV and systemic mycosis in South Africa (Kenyon *et al.*, 2013), subsequent morphological and phylogenetic observations led to reclassification as *Emergomyces africanus* (Dukik *et al.*, 2017), which is now the most frequently diagnosed cause of dimorphic infection in South Africa with an estimated 100 cases annually (Maphanga *et al.*, 2017; Schwartz *et al.*, 2018a). Other similar species have been reported worldwide but appear to be less important (Schwartz *et al.*, 2019). The ecological niche is unknown but based on molecular detection the mycelial form of *Es. africanus* may have a reservoir in soil (Schwartz *et al.*, 2018b). Transmission and pathophysiology are thought to be similar to that of other pathogens in the family Ajellomycetaceae.

Clinical Presentation

Emergomycosis occurs almost exclusively in advanced HIV. In the largest published case series median CD4 cell count was 16 cells/μL (interquartile range 6–60) and the majority of patients were either ART-naïve or failing ART; recent initiation (within 4 weeks of presentation) of ART has been associated with emergomycosis suggesting possible unmasking IRIS. Clinical presentation may be indistinguishable from other opportunistic diseases, including other dimorphic fungal infections, creating diagnostic challenges. Fever and cutaneous lesions are almost universal, and most patients have subclinical pulmonary involvement

Fig. 3 Clinical, radiological, and histological appearance of disseminated emergomycosis. 34-year-old man with HIV and CD4 cell count 6 cells/mm³ after interrupting ART, presented with fever, rash, weight loss, and cholestatic hepatitis. On examination there were widespread papular erythematous lesions (Figs. A – C). CXR showed subtle bilateral nodular infiltrates (Figure D). Biopsy of a skin lesion demonstrated granulomatous inflammation and intracellular yeasts on H&E (Figs. E and F) and PAS (Figure G) staining.

evidenced by radiographic abnormalities on chest X-ray (diffuse and focal infiltrates, lobar atelectasis, and hilar adenopathy) (Schwartz *et al.*, 2017; Kenyon *et al.*, 2013). Skin involvement is usually generalized with heterogeneous morphological features including papules, plaques, nodules, ulcers, and hyperpigmented patches (Schwartz *et al.*, 2015, 2017) (Fig. 3(A–D)). Hepatomegaly and intraabdominal lymphadenopathy are common (Schwartz *et al.*, 2017). Paradoxical IRIS has been described with worsening of cutaneous lesions approximately 4 months after initiating effective ART (Crombie *et al.*, 2018).

Diagnosis

Emergomycosis should be considered in all patients from southern Africa presenting with advanced HIV, cutaneous lesions, and fever. Skin biopsy for histopathological examination and fungal culture is the diagnostic procedure of choice, supplemented by fungal blood cultures (fungaemia occurs in up to 50% of cases) (Schwartz *et al.*, 2017; Kenyon *et al.*, 2013). Bone marrow aspiration and biopsy also has good diagnostic yield (Schwartz *et al.*, 2015). The finding of PAS-positive intracellular yeasts with granulomatous or suppurative dermal inflammatory infiltrate on tissue biopsy is supportive but does not distinguish emergomycosis from other HIV-associated dimorphic fungal infections. In tissue, *Es. africanus* yeasts are small globose or oval measuring 2–7 µm in diameter, often exhibiting single narrow-based budding; inflammation may be absent in severely immunocompromised patients (Govender and Grayson, 2019). Definitive diagnosis requires molecular identification from a clinical sample or positive culture. Indirect diagnostic tests such as 1,3-β-D-glucan and *Histoplasma* galactomannan urine antigen assay may be positive but appear to have poor discriminatory value (Schwartz *et al.*, 2015). It is important to screen for tuberculosis in patients with suspected emergomycosis, as these conditions are difficult to distinguish and may co-exist.

Management

The case fatality of emergomycosis is up to 40% even with antifungal therapy (Schwartz *et al.*, 2017; Kenyon *et al.*, 2013; Maphanga *et al.*, 2017). The recommended antifungal treatment is similar to other endemic mycoses in immunocompromised patients: amphotericin B deoxycholate dosed 1 mg/kg daily or, where possible, liposomal amphotericin B dosed at 3 mg/kg daily for 10–14 days, followed by oral itraconazole for at least 1 year. Voriconazole and posaconazole have in vitro activity against *Es. africanus* and are alternative options for consolidation/maintenance therapy (Maphanga *et al.*, 2017). Fluconazole is slightly less active in vitro but may be considered if other triazole agents are unavailable or contraindicated, preferably after confirmation of susceptibility.

ART should be initiated within 2 weeks. There are important pharmacokinetic drug-drug interactions between itraconazole and antiretrovirals: non-nucleoside reverse transcriptase inhibitors should be avoided, and itraconazole dose should be reduced when co-administered with boosted protease inhibitors (Schwartz and Wasserman, 2017). Dolutegravir is unlikely to result in drug interactions and is an alternative for patients who require itraconazole.

Talaromycosis

Epidemiology

Talaromycosis, caused by the dimorphic fungus *Talaromyces marneffei* (Tm), is a leading cause of AIDS-related mycoses in Southeast Asia (Limper et al., 2017), with an estimated 17,300 new infections causing 4900 deaths each year (Ning et al., 2020). In highly-endemic regions in northern Thailand, Vietnam, and southern China, talaromycosis is a leading cause of AIDS-related opportunistic infections, accounting for 4%–20% of HIV admissions (Jiang et al., 2019; Le et al., 2011; Hu et al., 2012; Supparatpinyo et al., 1992), with up to 50% mortality in patients with and without HIV (Jiang et al., 2019; Le et al., 2011; Kawila et al., 2013). Advanced HIV disease (CD4 count < 100 cells/ μ L) is the main driver of talaromycosis incidence (Le et al., 2011; Hu et al., 2012; Supparatpinyo et al., 1992), both of which remain prevalent in the ART era. Talaromycosis is increasingly reported in persons with a primary immunodeficiency condition due to idiopathic CD4 lymphopenia, anti-interferon- γ autoantibody, mutations in CYBB, CD40L, or gain-of-function mutation in the STAT1/STAT3 pathways (Chan et al., 2016), and is emerging in the general population due to increased incidence of malignancies and increased use of immunosuppressive therapy and organ transplantation (Chan et al., 2016). To date, talaromycosis has been reported in 20 countries spanning 6 continents outside of the endemic region due to travel and immigration (Ning et al., 2020; Antinori et al., 2006; Cristofaro and Mileno, 2006).

Tm has been cultured from the soil and in internal organs of wild bamboo rat species living in the highlands of Southeast Asia (Cao et al., 2011; Huang et al., 2015). Human infection occurs via inhalation of fungal spores and is associated with occupation in cultivation of plants and livestock (Chariyalertsak et al., 1997; Le et al., 2015) and residence in or travel to highland regions of Southeast Asia (Le et al., 2015). Incidence increases by 30%–50% during the rainy and humid months (Le et al., 2011; Chariyalertsak et al., 1996), suggesting that humidity facilitates expansion of the environmental reservoir, resulting in increased exposure and new infections. Reactivation of latent infection can occur up to 7 years after exposure (Cristofaro and Mileno, 2006; Antinori et al., 2006; De Monte et al., 2014).

Clinical Presentation

Disseminated infection involving the reticuloendothelial system, lungs, gastrointestinal tract, blood stream, and skin is the most common manifestation of talaromycosis in patients with advanced HIV disease (Limper et al., 2017). The subacute onset and generalized symptoms of fever, weight loss, and fatigue are indistinguishable from HIV wasting syndrome, tuberculosis, salmonellosis, and other systemic mycoses. The characteristic central-necrotic skin lesions on the face, trunk, and extremities, seen in 40%–70% of patients, are the hallmark yet late manifestations of talaromycosis (Fig. 1(D)) (Le et al., 2011; Chen et al., 2017).

Hepatosplenomegaly is present in 70% of patients. An acute pulmonary syndrome of cough, dyspnea, and infiltrates on chest X-ray is present in 40% of patients and is associated with a more rapid disease progression and a higher risk of death (Le et al., 2011, 2017). Acute CNS infection was seen in 21 of 677 (3%) of patients in one case series, with a mortality of 80% (Le et al., 2010). Common laboratory abnormalities include anemia, thrombocytopenia, and transaminitis.

Localized infections are more commonly seen in non-HIV infected patients. These include chronic pulmonary cavity lesions, obstructive tracheal lesions, pericarditis with pericardial effusion, osteoarticular lesions, abdominal abscess, genital chancroid, and cutaneous ulcers (De Monte et al., 2014; Saadiah et al., 1999; Annam et al., 2007; George et al., 2008; Louthrenoo et al., 1994; Luo et al., 2011; Pun and Fang, 2000).

Diagnosis

The diagnosis of talaromycosis is established by cultures of Tm from blood or clinical specimens, which takes 4–14 days and requires demonstration of temperature dimorphism (Fig. 4). An early presumptive diagnosis can be made by histopathological examination of skin lesions or other biopsy materials. Identification of extracellular and intra-macrophage oval-round yeast cells that divide by binary fission, resulting in a midline septum, discriminate Tm from other budding yeasts (Fig. 4). Tm can also be identified by microscopic examination of a Wright's-stained peripheral blood smear (Supparatpinyo and Sirisanthana, 1994). Culture yield is highest in the bone marrow (100%), followed by skin lesions (90%), and blood (70%) (Le et al., 2011; Supparatpinyo et al., 1992). The Matrix-Assisted Laser Desorption/Ionization-Time of Flight (MALDI-TOF) method has been used to identify Tm from cultured specimens.

Real-time PCR assays targeting the fungal ribosome and *MP1* genes have a high specificity (100%) but limited sensitivity (60%–70%) (Hien et al., 2016; Li et al., 2020; Lu et al., 2016; Pornprasert et al., 2009). Antigen-detection enzyme immunoassays (EIAs) using the Mp1p and 4D1 monoclonal antibodies are promising rapid diagnostics (Thu et al., 2020; Prakrit et al., 2016). In a

Fig. 4 *Talaromyces marneffei* subcultures from the bone marrow of a HIV-infected patient with talaromycosis. At 25°C, *T. marneffei* produces powdery greenish mold colonies and a bright red pigment that diffuses into the Sabouraud Dextrose Agar medium. Tape preparation of the mold colonies shows septate hyphae with conidiophores bearing phialides and round conidia under the microscope. At 37°C, *T. marneffei* produces white yeast colonies without the red pigmentation. Microscopic examination shows oval yeast cells, one with a central septum (arrow).

large validation study (372 culture-confirmed cases, 517 controls), the M1p1 EIA was more sensitive than blood culture (86.3% vs. 72.8%) with a specificity of 98% (Thu *et al.*, 2020). Antigen is detected in urine as well as in plasma samples and can detect occult culture-negative infections that are subsequently confirmed by bone marrow cultures (Ly *et al.*, 2020). The Mp1p EIA is being evaluated prospectively as a rapid diagnostic test and as a screening tool for pre-clinical talaromycosis (clinicaltrials.gov: NCT04033120). Point-of-care platforms are being developed which will enable testing and screening for talaromycosis in clinic and community settings.

Management

Treating disease

Induction therapy with amphotericin B deoxycholate (AmBd) at 0.7 mg/kg/day for 2 weeks has been shown in a small, non-comparative study ($n = 74$) in Thailand to have a clinical and mycologic success rate of 97% (Sirisanthana *et al.*, 1998). In a multi-center randomized controlled trial in Vietnam (IVAP, $n = 440$), induction therapy with AmBd was superior to itraconazole with respect to six-month mortality (11.3% versus 21.0%), fungal clearance from blood (99% clearance by day 7 versus 67%), rates of disease relapse and IRIS (Le *et al.*, 2017). These studies provide high-quality evidence for international guidelines recommending induction therapy (2 weeks) with amphotericin B (liposomal or deoxycholate, depending on availability) regardless of disease severity. Induction therapy is followed by consolidation (10 weeks) and maintenance therapy with itraconazole (or voriconazole) until CD4 count is above 100 cells/mm³ for 6 months (The National Institute of Health, and the HIV Medicine Association of the Infectious Diseases Society of America, 2019). The IVAP trial also suggested that 7 days' amphotericin may be adequate for induction therapy: a phase II trial is being planned in Vietnam.

Primary and secondary prophylaxis

Primary prophylaxis with itraconazole has been shown to reduce the incidence of talaromycosis and other invasive fungal infections in a small randomized trial ($n = 63$) (Chariyalertsak *et al.*, 2002). The study was not powered to detect a mortality benefit and was conducted prior to the ART era. For these limitations and for concerns of long-term toxicity, drug-drug interactions, and cost, primary prophylaxis is not recommended (see footnote).

Secondary prophylaxis with itraconazole 200 mg daily has been shown in a double-blinded placebo-controlled trial ($n = 71$) to reduce relapse rate from 57% to 0% (Supparatpinyo *et al.*, 1998). Optimal time to stop secondary prophylaxis is unknown, but a retrospective study ($n = 33$) reported no relapse in patients with a CD4 count > 100 cells/mm³ on ART (Chaiwarith *et al.*, 2007).

Timing of ART

The optimal time to start ART is unknown. In the IVAP trial, the median time to ART initiation was 3 weeks (range 1–5 weeks). Paradoxical IRIS events occurred only in the itraconazole arm (11.4%), suggesting that ART can be safely initiated as early as 1 week after effective induction therapy with amphotericin (Le *et al.*, 2017).

Fungal Infections in Transplant Recipients

Jeremy S Nel, University of the Witwatersrand, Johannesburg, South Africa

Anne Lachiewicz and David Van Duin, University of North Carolina, Chapel Hill, NC, United States

Introduction

Fungi are for the most part soil dwelling organisms that are pathogens of plants, insects and ectothermic vertebrates, but not mammals. The fact that even pathogenic fungi are generally not spread from human to human argues against any substantial selection for virulence in humans. Rather, the virulence displayed is largely an “accidental” byproduct of selection for survival and replication inside natural predators such as amoebae (Casadevall *et al.*, 2019). An impaired immune system alters the balance of forces, however, and permits the establishment of opportunistic fungal infections in hosts where this would not otherwise be possible. Thus, transplant recipients are at substantially greater risk of almost all fungal infections compared with immunocompetent hosts.

Transplant recipients can be broadly divided into two main groups: hematopoietic stem cell transplant (HSCT) recipients and solid organ transplant (SOT) recipients. Although there is substantial overlap, differences exist in the relative incidences of specific fungal infections between the two groups, reflecting differing immune deficits and immunosuppression regimens, as well as factors such as the presence or absence of myeloablation. In SOT recipients, invasive candidiasis accounts for > 50% of invasive fungal infections, followed by invasive aspergillosis (19%), cryptococcosis (8%), non-*Aspergillus* molds (8%), endemic fungi (5%) and mucormycosis (2%) (Pappas *et al.*, 2010). By contrast, HSCT recipients suffer from more invasive aspergillosis (43%) and mucormycosis (8%) than SOT recipients, but proportionately less candidiasis (28%), and cryptococcosis is extremely rare (Kontoyiannis *et al.*, 2010; Sun *et al.*, 2009).

The various fungal infections also differ by their median time to infection after transplant. In SOT recipients, the vast majority of early invasive fungal disease (≤ 90 days) is comprised of candidiasis and invasive aspergillosis, whereas the median times to infection for endemic mycoses, non-*Aspergillus* molds and cryptococcosis are all a year or more (Pappas *et al.*, 2010). Invasive fungal infections in HSCT recipients tend to occur earlier, perhaps as a result of the greater initial immunosuppression inherent in HSCT compared to most SOT. In one large-scale study, the median times of all invasive fungal infections was less than 180 days in HSCT recipients (Kyvernitakis *et al.*, 2016; Kontoyiannis *et al.*, 2010).

A major goal of care following transplantation is the prevention of fungal infections. To this end, most transplant recipients receive some form of antifungal prophylaxis in the immediate post-transplant period. The particular prophylaxis regimen is tailored to the patient, the organ transplanted and the immunosuppressive regimen given.

In this chapter, we review the major fungal infections in transplant recipients.

Candidiasis

Candida species are a normal constituent of the human gastrointestinal tract's flora. Estimates of asymptomatic *Candida albicans* intestinal carriage in humans range from 30% to 60%, and other *Candida* species such as *C. parapsilosis*, *C. glabrata* and *C. tropicalis* are also frequently found in the gastrointestinal tract in healthy individuals (Hallen-Adams and Suhr, 2017). To cause invasive disease *Candida* must either traverse the gastrointestinal mucosa or enter the body via a defect in one of the body's anatomical barriers, such as via central venous catheters (Koh *et al.*, 2008).

The cells of the innate immune system, particularly neutrophils, are required to prevent invasive candidiasis (Gazendam *et al.*, 2014; Fradin *et al.*, 2005; Koh *et al.*, 2008). Thus, neutropenia is among the strongest risk factors for candidemia and other forms of invasive disease. By contrast, humoral immunity appears to play no significant protective role in this regard, and a Th17-based immunity is important in controlling only mucosal candidiasis (Gazendam *et al.*, 2014). Thus, patients with impaired Th17 responses due to HIV may develop esophageal candidiasis, but HIV does not directly increase rates of invasive candidiasis like neutropenia does.

Candida blood stream infection is the predominant form of invasive candidiasis. Once in the blood stream, the organism may disseminate to other organs such as the eye, heart, skin, brain or bones. Hepatosplenic candidiasis is a rare syndrome particular to neutropenic hosts that occurs as their neutrophil counts begin to recover. In essence, hepatosplenic candidiasis is a form of *Candida* immune reconstitution inflammatory syndrome (IRIS). A fever that persists after neutrophil recovery should prompt consideration of this syndrome, which frequently involves the liver and spleen, though other organs such as the kidney may also be affected. Abdominal imaging may reveal small abscesses in the involved organs, but blood cultures are frequently negative at the time of diagnosis (Pagano *et al.*, 2002).

The species responsible for candidemia have been well described, though considerable shifts have taken place worldwide over the past two decades (Lamoth *et al.*, 2018). Although historically the most common species was *C. albicans*, this species now comprises less than 50% of *Candida* infections in many countries, including the United States. Correspondingly, a higher proportion of non-*albicans* is now seen, and in the USA, much of this is due to *C. glabrata* and *C. parapsilosis* (Lamoth *et al.*, 2018). Of specific concern is the worldwide emergence of *C. auris*. This organism has several adaptations that make it a fearsome nosocomial pathogen, including its ability to colonize the skin (unlike other *Candida* species), the production of biofilms,

resistance to several chemical disinfectants, and the ability to survive for prolonged periods in the immediate environment around infected or colonized patients (Cadnum *et al.*, 2017; Sherry *et al.*, 2017; Eyre *et al.*, 2018). *C. auris* is frequently resistant to one or more antifungals and has been shown to be responsible for several recent nosocomial outbreaks.

Diagnosis

Mucocutaneous candidiasis can usually be identified clinically. The classic appearance is the so-called pseudomembranous form, characterized by white curd-like plaques that can be easily scraped away to reveal a red, inflamed mucosal surface beneath. The signs and symptoms of invasive candidiasis depend somewhat on whether the transplant patient is neutropenic or not. Symptoms and signs of acute infection in severely neutropenic patients are notoriously insensitive. Redness, pain, swelling, fluctuance and local heat are all less prevalent in hosts with neutropenia (Valdivieso *et al.*, 1977). Laboratory and radiological tests may also be much less sensitive. For instance, in one study of neutropenic patients with cancer who had a UTI, only 11% had pyuria (Sickles *et al.*, 1975). In another study of neutropenic patients with pneumonia, 40% had normal radiograph, and just 8% had neutrophils on sputum Gram stain (Valdivieso *et al.*, 1977). Thus, a high index of suspicion may be required to diagnose *Candida* infections in the neutropenic host.

Blood cultures appear to be ~75% sensitive for candidemia, and are recommended whenever the condition is suspected (Clancy and Nguyen, 2013). Importantly, candidiasis of a particular organ may not be associated with candidemia at the time of presentation. The sensitivity of blood cultures for invasive candidiasis as a whole is probably closer to 50% (Clancy and Nguyen, 2013).

Nonculture methods include β -D-glucan (BDG), polymerase chain reaction (PCR), or T2 magnetic resonance technology. A recent meta-analysis pegged the sensitivity of BDG for invasive candidiasis at 75% (Karageorgopoulos *et al.*, 2011). In cases of deep-seated *Candida* infection, BDG may be positive days before blood cultures are (Tissot *et al.*, 2013). False positives are common however, and can result from things as diverse as bacteremia, surgical gauze, mucositis and some intravenous antibiotics, such as amoxicillin-clavulanate.

PCR assays on blood samples show great promise, with a recent meta-analysis reporting a sensitivity of 95% and specificity of 92% for invasive candidiasis (Avni *et al.*, 2011). A further advantage of PCR is its ability to rapidly provide species-level identification though cultures are still needed to determine drug susceptibilities.

T2 magnetic resonance diagnostics combine molecular amplification methods with T2 magnetic resonance measurement and are able to provide accurate results within 3–5 h. The assay can be run directly off whole blood. One study showed a sensitivity of 91% and a specificity of 99.4% when compared to blood cultures (Mylonakis *et al.*, 2015).

Treatment

Prompt antifungal therapy is vital in treating invasive candidiasis in general. A delay in administering appropriate antifungal therapy within 12–24 h has persistently been found to be an independent risk factor for mortality in candidemia (Morrell *et al.*, 2005; Kollef *et al.*, 2012; Garey *et al.*, 2006). In neutropenic patients in particular, candidemia is almost always life-threatening, particularly if the neutropenia is prolonged such as following induction therapy for hematological malignancies (Pappas *et al.*, 2016).

Oral candidiasis can be treated with a topical antifungal agent (e.g., nystatin swish and swallow). Severe cases of oral disease or nonresponsive cases can be given oral fluconazole. By contrast, patients thought to have invasive candidiasis should be commenced empirically on an echinocandin. The particular echinocandin selected usually depends primarily on cost and availability. Azole-resistant *Candida* species are too frequent for fluconazole to be recommended as initial therapy in most centers, particularly amongst neutropenic patients. In institutions with low rates of fluconazole resistance however, it may be a reasonable alternative in patients who are not critically ill and have had no prior azole exposure (Pappas *et al.*, 2016). An alternative to echinocandins as empiric therapy is amphotericin B. However, even the liposomal form of amphotericin B is tolerated far less well than the echinocandins are, precluding its use as a front-line drug.

If fluconazole susceptibility of the *Candida* species is demonstrated, the patient can be stepped down to fluconazole therapy when clinically stable. In most patients, intravenous fluconazole therapy is unnecessary, since the oral bioavailability of fluconazole is excellent.

Where possible, central venous catheters should be removed. The evidence for catheter removal in neutropenic patients is less compelling than for non-neutropenic patients, however (Pappas *et al.*, 2016). One likely reason is that the venous catheter is less likely to be the source of the candidemia in neutropenic patients, in whom gut translocation is a more common source. Nonetheless, any indwelling central catheters can become secondarily colonized during candidemic episodes and thereby act as a nidus for relapse after completion of therapy.

Endophthalmitis is an important complication that should be actively sought out in all cases of candidemia by means of a dilated fundoscopic examination (Pappas *et al.*, 2016; Kullberg *et al.*, 2011). Amongst studies from the 1990s onwards, intraocular candidiasis was found in approximately 7% of candidemic patients (Vinikoor *et al.*, 2013). Signs of endophthalmitis are usually minimal during neutropenic episodes, and so fundoscopy should be performed only once the neutrophil count has recovered (Pappas *et al.*, 2016).

The optimal duration of antifungal therapy for candidemia is unknown, but in the absence of randomized control trial data, a duration of 14 days after clearance of blood cultures is usually recommended (Pappas *et al.*, 2016). For those patients who are still neutropenic by day 14, antifungal therapy should generally be continued until neutrophil recovery occurs. Efforts to shorten the anticipated period of neutropenia, by granulocyte colony-stimulating factor (G-CSF) administration, or G-CSF-mobilized granulocyte transfusions can be considered in individual cases where appropriate, although the evidence base supporting these interventions is extremely limited.

The duration of therapy for other forms of invasive candidiasis depends on the site but is generally substantially longer than 14 days. Cases requiring special consideration include:

- (1) *Candida endophthalmitis* – Echinocandins do not penetrate the eye well, and so fluconazole or voriconazole are usually used orally or intravenously. Amphotericin B can be used as an alternative in resistant cases. Endophthalmitis needs a minimum of 4–6 weeks of therapy and may sometimes require intravitreal antifungals and/or a vitrectomy additionally. Co-management with an ophthalmologist is strongly recommended.
- (2) *Disease involving the central nervous system (CNS)* – Echinocandins have poor CNS penetration, and probably do not achieve high enough drug levels with conventional doses to treat CNS infections reliably (Pappas *et al.*, 2016; Hope *et al.*, 2008). Thus, for CNS disease, amphotericin B is given initially, sometimes with flucytosine in addition. Once the patient shows a response to this regimen, they may be switched to fluconazole (if susceptibilities permit) and continue this regimen until signs, symptoms and radiological abnormalities have all resolved.
- (3) *Urinary tract infections* – Attempting to distinguish a urinary tract infection from colonization by means of urinary white cells is futile in neutropenic patients, who cannot mount a local neutrophil response (Sickles *et al.*, 1975). In those patients requiring treatment, echinocandins do not penetrate the urinary tract well, and thus either fluconazole or, in fluconazole-resistant cases, amphotericin B, should be used. The urinary catheter should be removed in all cases where this is feasible. Amphotericin B bladder washes are a treatment of last resort for *Candida* cystitis when neither fluconazole nor systemic amphotericin B can be used.
- (4) *Hepatosplenic candidiasis* – this rare but important syndrome requires prolonged therapy until all lesions have resolved radiographically. This often takes several months. An echinocandin or liposomal amphotericin B should be used as initial therapy, stepping down to fluconazole (if susceptibilities permit) once the patient shows an initial response. Because this is essentially an IRIS response, some patients have been reported to show a symptomatic improvement with the addition of corticosteroids or nonsteroidal anti-inflammatory drugs. However, the evidence for anti-inflammatory agents is too limited for them to be routinely recommended.

Prophylaxis

Neutropenia from cancer-related immunosuppression warrants antifungal prophylaxis if it is profound ($<0.1 \times 10^9/L$) and protracted (≥ 7 days). Either an oral azole or an echinocandin is recommended. For *Candida* prophylaxis, fluconazole is sufficient (in contrast to empiric treatment regimens). However, in practice, a mold-active triazole such as posaconazole, voriconazole, or isavuconazole is often used for broader antifungal prophylaxis. Neutropenia from causes other than cancer-related immunosuppression does not generally warrant prophylaxis.

Aspergillosis

Aspergillus species account for the majority of mold infections in transplant recipients, making up 76% and 81% of mold infections in HSCT recipients and SOT recipients respectively (Pappas *et al.*, 2010). *Aspergillus fumigatus* is the species most commonly associated with disease in transplant patients, but *A. flavus*, *A. niger*, and *A. terreus* are also frequently identified (Vazquez *et al.*, 2013).

Aspergillus is a ubiquitous mold, and infection is acquired in most cases through inhalation of its conidia. Infection can more rarely be acquired by consumption of contaminated food products, or by direct cutaneous inoculation following a break in the skin barrier (as seen in burn or trauma victims for instance) (Patterson *et al.*, 2016). Nosocomial transmission has also been described (Pegues *et al.*, 2001). The risk of aspergillosis is higher in HSCT recipients than SOT recipients, probably as a result of performing HLA-mismatched or unrelated HSCTs, in whom more intense immunosuppression is required (Vazquez *et al.*, 2013). Within SOT recipients, lung recipients are at particular risk of contracting aspergillosis due to both the chronic exposure of the transplanted lung to the external environment and the transplanted lung's anatomical and functional abnormalities (such as anastomotic sites) (Shoham and Marr, 2012).

Aspergillus spp. may colonize the airways without tissue invasion. Colonization is particularly frequent and important in lung transplant recipients, in whom it predisposes to subsequent invasive disease (Silveira and Husain, 2007). Invasive aspergillosis (IA) refers to invasion of tissue due by hyphae due to *Aspergillus* species (Kosmidis and Denning, 2015). The most common site of involvement is the lung and, in lung transplant recipients, the tracheobronchial tree (at the anastomotic site). Neutropenia is the classic risk factor for IA, and such patients usually have the most aggressive form of IA, where visible disease progression may be noticeable over the course of several days (Kosmidis and Denning, 2015). Angioinvasion is common,

Fig. 1 Halo sign (arrow) – a central nodule surrounded by a hazy ground glass infiltrate. The halo sign represents an area of pulmonary infarction (the nodule) with surrounding hemorrhage (the ground glass infiltrate). Although somewhat nonspecific, in the neutropenic host its strongest association is with invasive aspergillosis.

facilitating disease dissemination to distant sites such as the skin, brain, or eyes. Non-neutropenic patients can also develop IA, though the course is often more subacute (over weeks to months), usually without angioinvasion or fever. Risk factors for this include non-neutropenic HCST and SOT recipients, HIV, COPD, corticosteroid use, critically ill patients in the ICU, and severe influenza infection (Vanderbeke *et al.*, 2018).

Diagnosis

The diagnosis of IA can be extremely challenging. In HSCT recipients a characteristic radiological finding is the “halo sign” (Fig. 1), but this has a low sensitivity in SOT recipients (Singh and Husain, 2003). Despite angioinvasion, blood cultures are almost always negative. Hyphal invasion of tissue together with culture of *Aspergillus* from the same tissue is the gold standard, but obtaining these samples in critically ill patients may be challenging (Silveira and Husain, 2007). Given that the lung is the most frequently involved organ, bronchoalveolar lavage (BAL) and/or lung biopsy often provides the highest diagnostic yield, though any tissue may be sampled when involved (e.g., skin). *Aspergillus* grows readily on most media, but the yield is increased if plated on to dedicated fungal growth media (Shoham and Marr, 2012). *Aspergillus*-specific galactomannan assays can be used on both BAL and serum specimens, but BAL specimens generally demonstrate a higher sensitivity than serum ones. The sensitivity of the galactomannan test ranges from 60% to 93%, depending on the cut-off value used (higher sensitivities are seen with a cutoff of 0.5) (Kosmidis and Denning, 2015; Zou *et al.*, 2012). Serum β -D-glucan assays show comparable sensitivity, though they are much less specific. PCR offers great promise, but as with BAL cultures, it lacks the ability to distinguish colonization from infection.

Treatment

Treatment with voriconazole has been shown to be superior to amphotericin B with respect to both treatment success and 12-week survival (Herbrecht *et al.*, 2002). Recently, the SECURE trial demonstrated that isavuconazole was non-inferior to voriconazole for the treatment of *Aspergillus* and other filamentous molds (Maertens *et al.*, 2016b). Treatment is continued for a minimum of 6–12 weeks, depending on the patient’s immunosuppressive regimen, the site of disease and evidence of improvement. (Patterson *et al.*, 2016) Mortality from IA remains high however, with fewer than half of transplant recipients being alive 12 months after diagnosis. (Pappas *et al.*, 2010).

Prophylaxis

Prophylaxis is recommended for patients at high risk of aspergillosis, including patients with prolonged neutropenia, patients with graft-versus-host disease and lung transplant patients (Patterson *et al.*, 2016). Other SOT recipients may also be given *Aspergillus*

prophylaxis depending on institutional policy and individual patient risk factors. A mold-active azole such as voriconazole, posaconazole or itraconazole is usually chosen. In lung transplant recipients inhaled amphotericin B is sometimes used instead of or in addition to a systemic triazole.

Mucormycosis

Mucormycosis (previously known as zygomycosis), is an invasive fungal disease caused by fungi of the Mucorales order. The most commonly implicated species are *Rhizopus*, *Lichtheimia*, *Rhizomucor*, *Mucor* and *Cunninghamella*. These fungi are ubiquitous and found in decaying organic materials such as bread, fruit, vegetable matter, soil, compost and animal excreta. The usual mode of acquisition is by inhalation of the conidia, though direct inoculation following breaks in the skin barrier, or ingestion in patients with breaks in the gastrointestinal tract mucosa, are also described. The first line of defense are the host's macrophages and neutrophils, and impairment of this during periods of neutropenia or glucocorticoid use is a major risk factor for disease acquisition (Ibrahim *et al.*, 2012). Overall, the disease is more common in HSCT recipients than SOT recipients, and comprises 8% and 2% of invasive fungal infections in these two populations respectively (Armellino *et al.*, 2012).

Once established, mucormycosis runs an aggressive course marked by angioinvasion and consequent tissue infarction and dissemination. The main forms of disease that occur are pulmonary, rhinocerebral, sinus, cutaneous and gastrointestinal mucormycosis. The frequency of presenting site vary somewhat by transplant type. In HSCT recipients, pulmonary disease accounts for over half of all mucormycosis seen, whereas it makes up just over a third of cases seen in SOT recipients, in whom cutaneous and rhinocerebral disease makes up a proportionally greater percentage of cases (Roden *et al.*, 2005). When skin involvement is present, it usually represents the site of inoculation rather than haematogenous spread, unlike the case for many other filamentous fungi (Roden *et al.*, 2005).

Diagnosis

Infarction of involved tissues is the usual clinical finding (Fig. 2), with skin areas often appearing as eschars. Other clinical findings include pleuritic pain (lung involvement) or proptosis (extension into the orbital cavity). Though these findings are not specific for mucormycosis, the disease must remain high on the differential diagnosis in transplant recipients. Histopathologic specimens show characteristic broad hyphae with right-angle branching and few or no septae. There are no biochemical or serological biomarkers to aid in the diagnosis, and the culture yield is suboptimal (50%–71%) (Katragkou *et al.*, 2014). Overall, the diagnosis is confirmed ante mortem in fewer than half of cases.

Treatment

Key treatment principles are (1) aggressive surgical debridement of all necrotic tissue, (2) prompt antifungal therapy and (3) reversal of any predisposing factors if possible. Amphotericin B is the mainstay of the antifungal therapy. Combination therapy with an azole or an echinocandin is controversial but is often given in clinical practice (Reed *et al.*, 2008; Kyvernitakis *et al.*, 2016). Repeat surgical debridements are usually required, since there is a delay between fungal angioinvasion and visible necrosis.

Mortality from mucormycosis is exceedingly high, even in cases that are treated promptly and aggressively. In one large review of cases, 91% of HSCT recipients and of 48% of SOT recipients died during the course of their mucormycosis (Roden *et al.*, 2005).

Fig. 2 Area of palatal infarction (arrow) as a result of extension of rhinocerebral mucormycosis.

Cryptococcosis

Cryptococcosis is a relatively common cause of invasive fungal disease in SOT recipients, with an incidence of 0.3%–5% (Silveira and Husain, 2007). Interestingly, cryptococcal infection is exceedingly rare in HSCT recipients – a review in 2009 found only nine reported cases in the literature (Sun *et al.*, 2009). *Cryptococcus neoformans* accounts for the vast majority of cases of cryptococcosis. Its natural habitat appears to be soil contaminated with pigeon and other bird droppings as well as the decaying wood from certain trees, such as *Eucalyptus* trees, mopane trees and the baobab trees (Cogliati, 2013). Exposures and infections occur worldwide.

As with most other fungal infections in transplant recipients, the lungs are the usual portal of entry as well as a frequent site of disease. Disease can occur shortly after exposure or result from reactivation of an exposure many years previously. Cryptococcosis has also been transmitted from donor organs on rare occasions (Shoham and Marr, 2012). The usual radiographic changes are nodules, with or without cavitation, though a variety of other manifestations are also seen including pleural effusions, and even ARDS. The fungus has a particular tropism for the central nervous system, where it may cause a chronic meningitis, intracerebral cryptococcomas, or both. Headache, fever and mental status changes are frequent findings, though meningism is found in fewer than a third of patients (Silveira and Husain, 2007). In the Transplant-Associated Infection Surveillance Network's review of cases from 2001 to 2006, central nervous system involvement was seen in 45% of cases and disease limited to the lungs was seen in 39%. Interestingly, calcineurin inhibitors such as tacrolimus exhibit anti-cryptococcal activity, and a decreased incidence of CNS disease is seen in patients on these agents compared to transplant recipients on alternative immunosuppressant regimens (Silveira and Husain, 2007). After the lungs and CNS, the next most common site of involvement is the skin, where skin-colored papules and plaques can occur. Cutaneous lesions usually have a degree of central umbilication, appearing as a larger version of molluscum contagiosum. (Fig. 3) *Cryptococcus* may also cause cellulitis that is clinically similar to bacterial cellulitis. This entity should be suspected in transplant recipients with cellulitis that is unresponsive to antibacterials.

Diagnosis

Disseminated and CNS cryptococcosis in immunocompromised patients is usually detected by a serum cryptococcal antigen test, which has a sensitivity of >95% for both conditions. The diagnosis of central nervous system involvement can similarly be established by performing the antigen test on a CSF sample. The sensitivity in isolated pulmonary disease is lower, however, and a negative result does not rule the condition out (Aberg *et al.*, 1999). The fungus is also readily cultured from appropriate samples such as sputum, BAL fluid, or CSF. Of note, all transplant recipients with suspected or proven cryptococcosis outside the CNS should have a lumbar puncture to exclude occult CNS disease.

Fig. 3 Multiple umbilicated papules and plaques typical of cutaneous cryptococcosis.

Treatment

Treatment of cryptococcal meningitis in transplant recipients consists of induction therapy with a combination of amphotericin B and flucytosine for at least two weeks (Perfect *et al.*, 2010). This is followed by maintenance and consolidation therapy with fluconazole, the latter typically given for at least 6–12 months. The treatment duration may be extended if the patient's net state of immunosuppression is still high at that point. Mild cases of pulmonary disease can be treated with fluconazole alone, but more severe should be treated as for CNS disease (Perfect *et al.*, 2010).

Although case fatality rates of ~40% were historically described, mortality rates in more recent cohorts have roughly halved (Sun *et al.*, 2009). In addition to prompt antifungal therapy, a key component to managing cryptococcal meningitis successfully is to relieve elevated CSF pressures with repeated therapeutic lumbar punctures and/or temporary CSF shunts.

Endemic Fungal Infections

The endemic mycoses are a group of thermally dimorphic fungi that occupy discrete geographic niches. The principal diseases in this group are histoplasmosis, blastomycosis, coccidioidomycosis, sporotrichosis, paracoccidioidomycosis, talaromycosis and emerymycosis. The first four of these are found in North America. In the environment, the dimorphic fungi exist as molds, but at body temperature they transform into yeasts (or in the case of coccidioidomycosis, into a specialized structure called a spherule).

The incidence of all the dimorphic fungi is increased in transplant recipients. The usual way infection is acquired is by the inhalation of aerosolized conidia, often following disturbance of the soil or organic matter where the fungi are residing. In the lung, the host defenses frequently either clear or control the nascent infection, but this ability is attenuated in transplant recipients. Importantly, infection may be contained subclinically for many years, and only escape host immune control when the patient's immune system is depleted by solid organ transplantation, hematologic stem cell transplantation, immunosuppressant medications, old age, HIV or other immunocompromising conditions. Rarely, the infection may be inadvertently transmitted by an infected allograft. Donor-derived infection has been demonstrated in the case of histoplasmosis and coccidioidomycosis.

Detailed descriptions of each of these diseases are beyond the scope of this chapter, but the three most common dimorphic fungi seen in transplant recipients – histoplasmosis, blastomycosis and coccidioidomycosis – are summarized below.

Histoplasmosis

The preferred soil environment for *Histoplasma capsulatum* within the USA appears to be the Ohio, Mississippi and Missouri River basins. Parts of India, South East Asia, Australia and Africa are also endemic for the disease. Soil that has been enriched with bat and bird guano is a particularly rich environment for *Histoplasma* growth, and exposure has frequently been linked to spelunking, cleaning of attics, cleaning bird coops, and renovating buildings.

The Transplant-Associated Infection Surveillance Network (TRANSNET) reported 48 cases of histoplasmosis in SOT recipients and 4 in HCT recipients from 15 surveillance sites over 5 years from 2001 to 2006, making histoplasmosis the most frequent dimorphic pathogen in transplant recipients in the US (Kauffman *et al.*, 2014). The cumulative incidence in SOT recipients was 0.1% for the 12-month period following their transplants, and 0.02% for HSCT recipients.

In immune competent individuals, disease manifestations are largely confined to the lungs, which are the primary site of infection. Acute, subacute, or chronic pneumonias are common, and less frequently manifestations such as acute respiratory distress syndrome, broncholithiasis, and fibrosing mediastinitis can also be seen. However, in transplant recipients, diseases frequently disseminates widely to other sites in addition. These may include lymph nodes, the liver, spleen, bone marrow, skin, and gastrointestinal tract (Cuellar-Rodriguez *et al.*, 2009; Freifeld *et al.*, 2005). Symptoms are correspondingly attributable to organ enlargement, cytopenias from marrow infiltration or haemophagocytic lymphohistiocytosis, and the effects of cytokine production, such as fever, anorexia, loss of weight, and malaise.

The diagnostic test with the highest sensitivity for disseminated disease is the urine histoplasma antigen, with an estimated 93% sensitivity in SOT recipients (Nel *et al.*, 2018). Antigen testing may also be performed on the blood, BAL fluid, or CSF with variable sensitivity. False-positive results due to *Aspergillus* infection have been reported in SOT recipients (Vergidis *et al.*, 2012). Cultures from blood or tissues from affected sites have moderate sensitivity, but typically take 2–4 weeks to turn positive. Histologic specimens can provide a presumptive diagnosis by revealing typical intracellular clustering of small yeast-like organisms within macrophages and other phagocytes (Guarner and Brandt, 2011). *Histoplasma* may also appear to have a capsule on histopathologic specimens. PCR assays appear to be a promising diagnostic modality, but experience and availability with molecular testing is limited to date.

Treatment in disseminated histoplasmosis is typically with a lipid formulation amphotericin B for 1–2 weeks initially. When the patient demonstrates clinical improvement, the amphotericin can be switched to itraconazole for a duration of at least 12 months (Wheat *et al.*, 2007). Histoplasma antigen levels may be monitored serially to assess response to therapy, since a failure of the antigen level to decline is associated with treatment failure. In addition, antigen levels should be negative at the end of treatment, though some patients with persistent low-level antigenuria without evidence of active disease have had good clinical outcomes when their treatment was stopped (Wheat *et al.*, 2007; Goldman *et al.*, 2004). Histoplasmosis can relapse after treatment, and so urine antigen levels should also be checked periodically for the 6–12 months following treatment completion.

Blastomycosis

Blastomycosis in the USA is caused by one of two species, *Blastomyces dermatitidis* and *Blastomyces gilchristii*. The natural habitat of *Blastomyces* is largely unknown, though recent phylogeographic work has demonstrated a strong association with freshwater basins. In North America, endemic areas are the Ohio, Mississippi, Tennessee and Nelson River basins, as well as a small area surrounding the St Lawrence River. As with histoplasmosis, risk factors for blastomycosis are activities that disturb the soil in these regions, such as construction, fishing, or cutting trees or brush.

Blastomycosis is less common than histoplasmosis amongst transplant recipients – just 9 cases were described over a 5 year period in 15 surveillance sites in the USA (Kauffman *et al.*, 2014; Pappas *et al.*, 2010). While *Blastomyces* infection in immunocompetent patients is asymptomatic in approximately half of cases, transplant recipients develop symptomatic pulmonary disease in 80%–100% of infections (Grim *et al.*, 2012; Gauthier *et al.*, 2007). *Blastomyces* pneumonia may progress to acute respiratory distress syndrome (ARDS) and result in substantial residual lung damage. Disseminated disease is also frequent in transplant recipients. The skin (verrucous lesions, pustules, ulcers), bone (lytic lesions), genitourinary system (prostatitis, epididymitis) and central nervous system (meningitis or cerebral abscesses) are the most frequent extra-pulmonary sites (Kauffman and Miceli, 2015).

Blastomyces can be presumptively identified on tissue specimens by its large size, double-contoured walls and characteristic broad-based budding (Guarner and Brandt, 2011). *Blastomyces* is also readily cultured from sputum, BAL fluid and skin when these sites are involved. Cultures may take several weeks to turn positive however (Smith and Kauffman, 2010). A urine antigen test has a sensitivity of 76%–93%, though cross-reaction with other dimorphic fungi is frequent (Nel *et al.*, 2018).

As with histoplasmosis, initial therapy with amphotericin B is recommended for all immunocompromised patients, followed by itraconazole for at least 12 months.

Coccidioidomycosis

Two species of *Coccidioides* are responsible for human coccidioidomycosis: *C. immitis* and *C. posadasii*. The fungus is endemic in the hot, dry, arid and semiarid zones of California, Arizona, New Mexico and Texas, together with northern Mexico and smaller areas in South America. Sandstorms, construction work and military exercises are risk factors for acquiring coccidioidomycosis (Hage *et al.*, 2012).

9 cases of coccidioidomycosis were described in a 5 year period from the 15 surveillance sites in the Transplant-associated Infection Surveillance Network (TRANSNET) (Pappas *et al.*, 2010). Compared to immunocompetent patients, transplant recipients have a much higher rate of both symptomatic pulmonary disease and disseminated disease. Pulmonary disease mimics a community-acquired pneumonia, and the diagnosis is sometimes only suspected when the patient fails to improve on conventional antibiotics. The disease can progress to ARDS in severe cases. Common extra-pulmonary sites in disseminated disease include the CNS, liver, spleen, kidney, skin and joints (Blair and Logan, 2001).

Unlike other dimorphic fungi, the inhaled conidia transform not into yeasts but rather into a specialized structure called a spherule. Visualization of the spherule on tissue samples is therefore pathognomonic (Guarner and Brandt, 2011). Cultures from involved sites also grow more readily than most other dimorphic fungi, often within a week (Blair and Logan, 2001). The sensitivity of serology is lessened in transplant recipients, but a positive *Coccidioides* antibody result indicates active or recent disease since antibody levels become negative again after successful treatment (Galgiani *et al.*, 2016). Urine and serum antigen testing is moderately sensitive, though cross-reaction with antigens from other endemic mycoses occurs (Durkin *et al.*, 2008).

Mild cases of coccidioidomycosis can be treated with an azole alone, but most cases in transplant recipients require initial therapy with amphotericin B. Once the patient shows clinical improvement, the amphotericin can be transitioned to azole therapy for approximately 12 months. Fluconazole and itraconazole are the most commonly used azoles, with fluconazole often being favored due to its predictable pharmacokinetics and its less troublesome drug-drug interactions (Galgiani *et al.*, 2016).

Coccidioidomycosis has a strong propensity to relapse in transplant recipients, and so suppressive azole therapy (e.g., fluconazole 200–400 mg daily) is usually given indefinitely following completion of the treatment course in HSCT and SOT recipients, or at least until all immunosuppressant medication is withdrawn (Galgiani *et al.*, 2016). Similarly, life-long suppressive therapy is probably indicated for all transplant recipients with a prior history of coccidioidomycosis, or changes consistent with prior coccidioidomycosis on a chest radiograph of patients who live in endemic areas, or who are seropositive. Finally, transplant recipients living in an endemic area who have no evidence of active or prior coccidioidomycosis, a low-dose azole (e.g., fluconazole 200 mg daily) is recommended for 6–12 months to prevent de novo infection (Galgiani *et al.*, 2016).

Pneumocystis Pneumonia

Pneumocystis jirovecii is the causative agent for *Pneumocystis* pneumonia (PCP) in humans. A ubiquitous fungus, infection is acquired through inhalation. Most cases of PCP occur as a result of reactivation of latent infection, but human-to-human transmission has been demonstrated to occur amongst transplant recipients (Vindrios *et al.*, 2017; de Boer *et al.*, 2007). The incidence in SOT recipients is approximately 0.3%–2.6%, and approaches 0% in HSCT recipients provided appropriate prophylaxis is taken (Iriart *et al.*, 2015; Cordonnier *et al.*, 2016).

PCP in transplant recipients presents much more acutely than it does in patients with HIV. (Iriart *et al.*, 2015) Disease is almost always confined entirely to the lungs, with dyspnea, hypoxemia, non-productive cough and fever being the predominant symptoms. Chest auscultation is often unremarkable even in the face of extensive pulmonary infiltration. Plain films may be normal in ~10% of cases, but computed tomography (CT) scans of the lung almost always shows abnormalities. The typical changes are of bilateral patchy areas of ground glass infiltration often abutting normal areas of lung, with a mid- to lower-zone predominance (Kanne *et al.*, 2012). Pleural effusions and lymphadenopathy are unusual in PCP since the fungus adheres to type I pneumocytes in the alveoli rather than invading into the parenchyma.

Diagnosis

Pneumocystis jirovecii cannot be cultured on standard laboratory media and thus diagnosis rests on visualization of the organism. Giemsa stains, silver stains, or immunofluorescent stains are required for this. BAL fluid is the optimal sample to test, with a sensitivity of 80%–97% using any of the staining methods. Induced sputum is less invasive alternative, but one with a correspondingly lower sensitivity (30%–55%) (Rodriguez and Fishman, 2004). An alternative to direct visualization is PCR. PCR assays have extremely good sensitivity and a correspondingly high negative predictive value. However, since *Pneumocystis jirovecii* frequently colonizes human airways without causing disease, false positive results are a concern (Iriart *et al.*, 2015). Using single-copy gene targets may allow for a better distinction between colonization and infection (Wilson *et al.*, 2011). Serum β -D-glucan assays are more readily available than BAL fluid and are sensitive (>90%) but not specific for PCP.

Treatment

Trimethoprim-sulfamethoxazole (TMP-SMX) is the agent of choice to treat PCP. Alternatives for patients who cannot tolerate TMP-SMX include intravenous pentamidine or a combination of primaquine and clindamycin (Martin *et al.*, 2013). Patients who are significantly hypoxemic ($\text{pAO}_2 < 70$ mmHg) should receive adjunctive corticosteroids, since PCP symptoms may otherwise tend to worsen when treatment is initiated.

Prophylaxis

Prophylactic doses of TMP-SMX are extremely effective at preventing PCP, such that almost all infections in transplant recipients occur only after TMP-SMX is stopped (whether per institutional protocol or due to patient nonadherence) (Overgaard and Helweg-Larsen, 2007). The optimal duration of TMP-SMX prophylaxis is much debated, and probably varies by transplant type and immunosuppression regimen. For most SOT recipients, 6–12 months of prophylactic TMP-SMX is recommended, though lung transplant recipients in particular may require lifelong prophylaxis (Martin *et al.*, 2013). Allogeneic HSCT recipients should receive TMP-SMX for a minimum of 6 months starting from engraftment or as long as their immunosuppression is ongoing, whichever is longer. (Maertens *et al.*, 2016a).

Fungal Infections in Cancer Patients

Bruno P Granwehr and Dimitrios P Kontoyiannis, The University of Texas MD Anderson Cancer Center, Houston, TX, United States

Introduction

Fungi are a diverse group of organisms that cause a wide array of disease in humans. Fungi are associated with superficial infections of the skin or subcutaneous tissues, but may also cause invasive disease, even in immunocompetent hosts. In immunocompetent patients, a large inoculum of endemic fungi (e.g., *Coccidioides*) may cause severe invasive infection. In heavily immunocompromised hosts, such as patients with hematologic malignancies, even a low inoculum of opportunistic fungi (e.g., *Fusarium* species) results in severe disease. In the USA, fungal diseases were estimated to cost \$7.2 billion in 2017 (Benedict *et al.*, 2019b). This is divided between 75,033 hospitalizations costing \$4.5 billion and nearly 9 million outpatient visits, costing \$2.6 billion. Notably, opportunistic mycoses, such as aspergillosis, invasive candidiasis, pneumocystosis, and mucormycosis, are associated with the largest economic burden (Benedict *et al.*, 2019b).

The increased risk of invasive fungal infection in cancer patients is attributable to impairment of the immune system from the cancer itself, such as those with hematologic malignancies, or with structural lung damage from tumor invasion, but also due to the detrimental effects of various cancer treatments on the immune response. Patients who are severely immunocompromised by cancer treatment or stem cell transplant could develop uncommon opportunistic fungal infections. In addition, cancer patients may develop endemic fungal infections to which immunocompetent hosts are also susceptible, such as coccidioidomycosis or histoplasmosis.

Effects of Cancer Treatment on Immune Response to Fungal Infection

Cancer therapy is constantly changing. Traditional modalities, such as radiation, surgery, and cytotoxic chemotherapy have led to the revolution of therapeutics in cancer with monoclonal antibodies targeted against surface molecules on cancer cells and therapies which harness the immune response against cancer. These include checkpoint inhibitors (CPIs), which enhance the cellular immune response, targeting cancer cells, but may also result in immune-mediated injury to several organs (Fishman *et al.*, 2019). The impact of CPIs on the risk of fungal infection is a matter of debate, with animal models of histoplasmosis, candidiasis, aspergillosis, and cryptococcosis suggesting a benefit from PD-1 and PDL-1 inhibitors (Abers *et al.*, 2019). A recent study examined the impact of PD-1 inhibitor alone, and in combination with caspofungin, on a mouse model of invasive pulmonary aspergillosis (Wurster *et al.*, 2020). The PD-1 inhibitor alone improved survival, decreased tissue fungal burden, and also reduced markers of pulmonary inflammation. In addition, the combination of PD-1 inhibitor with immunomodulatory antifungal caspofungin led to an additional benefit in mortality, compared to either agent alone (Wurster *et al.*, 2020). CPIs may be of particular benefit in patients with chronic fungal infections refractory to therapy, such as invasive candidiasis, reversing “immune exhaustion” that is a common barrier to overcoming such infections. Insufficient clinical data, however, are available regarding impact of CPIs on opportunistic mold infection.

Ibrutinib and other kinase inhibitors are another class of agents used to treat cancers, including chronic lymphocytic leukemia (CLL), mantle cell lymphoma, and primary central nervous system (CNS) lymphoma. Although randomized clinical trials with these agents failed to demonstrate an increased risk of invasive fungal infections (IFI) (Chamilos *et al.*, 2018), several ibrutinib-related IFIs have been reported with the “real life” experience in CLL, especially CNS invasive aspergillosis, *Pneumocystis jirovecii* pneumonia, and cryptococcosis (Ruchlemer *et al.*, 2019).

Other novel cancer treatments include immunotherapy platforms, such as CAR-T cell and, more recently CAR-NK cell therapies. The conditioning therapy used to prepare patients with malignancy for these cell-based therapies, results in significant acute impairment of the immune response. Depending on the type and intensity of conditioning therapy and the underlying cancer, impairment of several elements of the immune system may be seen, lasting 6 months to 1 year. The impact of these therapies on risk of fungal infection is unclear, with current efforts to optimize prophylaxis, based on evolving understanding of risk stratification, including influence of the underlying cancer, prior cancer treatment, co-morbidities as well as the exposure to conditioning therapy in preparation for administration of CAR-T cells (Haidar *et al.*, 2019; Lewis and Kontoyiannis, 2020). In patients with hematologic malignancies, at highest risk of invasive fungal infection (IFI), efforts are ongoing to develop models to predict incidence of IFI (Stanzani *et al.*, 2019b). Future efforts to predict the patients at highest risk for severe IFI will provide guidance for which patients need prophylaxis and which patients benefit from surveillance with biomarkers without prophylaxis.

Opportunistic Fungal Infections

Invasive candidiasis (IC) remains the most common invasive fungal infection in patients with cancer, with *Candida* bloodstream infection the 2nd most common etiology of health-care associated bloodstream infection overall (Magill *et al.*, 2018). Candidiasis affects patients with compromise in skin and mucosal barriers. These barriers may be compromised by direct physical injury with

Table 1 Fungal infections in cancer patients

Organism	Clinical presentation	Treatment comments
<i>Candida</i> spp.	Thrush	● Remove CVC within 24 h of diagnosis for CVC-associated invasive candidiasis
	Esophageal candidiasis	● Eye exam (await neutrophil recovery to improve yield)
	Urinary tract infection	● Echocardiogram in patients with persistent Candidemia
	Candidemia	● Caspofungin for severe illness, may stepdown to fluconazole
	Disseminated candidiasis	
<i>Aspergillus</i> spp.	Pulmonary	● Voriconazole, isavuconazole, Amphotericin B
	Sinusitis	● Measure azole drug levels, especially voriconazole levels
	Skin infection	● CT sinus → if sinusitis present
	Disseminated	● Serial CT chest and serum Galactomannan are helpful in assessing response to treatment
<i>Cryptococcus</i> spp.	Pneumonia	● Serum Cryptococcus antigen
	CNS	● Amphotericin B 1st line for severe infection, with 5-flucytosine for meningitis
	Disseminated	● Fluconazole as initial therapy for less severe infection, may also be used for stepdown
<i>Fusarium</i> spp.		● Lumbar puncture, with repeat LP, if elevated CSF pressure
	Sinus infection	● Voriconazole 1st line treatment
	Pneumonia	● Posaconazole, Amphotericin B also options
	Skin infection	● Echinocandins, isavuconazole are not effective
	Dissemination	● Difficult to treat without recovery from neutropenia
<i>Mucorales</i> spp.	Rhinocerebral	● Amphotericin B, posaconazole, isavuconazole, are effective
	Pulmonary	● Surgical debridement and hyperbaric oxygen
	Gastrointestinal	● Difficult to treat without recovery from neutropenia
	Cutaneous	

indwelling vascular catheters and surgery (Tsay *et al.*, 2020). Cancer treatment, particularly cytotoxic cancer therapy, not only damages gastrointestinal mucosa, leading to translocation of organisms, but also leads to neutropenia, which impairs the immune response to invading organisms, including *Candida* species (Kullberg and Arendrup, 2015). Patients with invasive candidiasis develop persistent fever despite broad spectrum antibacterials, in context of neutropenia. As all other IFIs, a high index of suspicion is necessary to identify invasive candidiasis.

Several *Candida* species cause infection. *Candida albicans* remains the most common species, with high virulence, but low resistance. *Candida glabrata* is increasing in frequency, particularly in oncology patients, and is frequently resistant or tolerant to fluconazole (Farmakiotis and Kontoyiannis, 2017). The landscape of IC in patients with hematologic cancers on azole prophylaxis has changed dramatically in the last 20–30 years. Among leukemia patients with candidemia, at our tertiary center, approximately 1% of cases are attributable to *Candida albicans*, with *Candida parapsilosis* (32%) the most commonly isolated species, followed by *Candida tropicalis* (23%) and *Candida glabrata* (20%) (Wang *et al.*, 2015). This change in species has implications regarding empiric selection of antifungals, with 20.5% of isolates of *Candida glabrata* resistant to fluconazole, and 6.8% resistant to multiple classes of antifungals (Farmakiotis *et al.*, 2014).

Multiple clinical presentations are associated with candidiasis, from superficial infections to candidemia (Pappas *et al.*, 2016) (Table 1). Superficial infections include oropharyngeal candidiasis, esophagitis, and urinary tract infection (Pappas *et al.*, 2016). Oropharyngeal candidiasis, known as “thrush”, is the most common of superficial fungal infections associated with candidiasis, classically occurring in patients undergoing chemoradiation (Samonis *et al.*, 1998). The diagnosis is clinical, with identification of whitish plaques on the buccal mucosa, palate, or tongue that may be scraped off, revealing an erythematous base (Pappas *et al.*, 2016). Treatment consists of clotrimazole 10 mg troches or nystatin suspension for 7–14 days (Pappas *et al.*, 2016).

Esophageal candidiasis should be considered in cancer patients with dysphagia, retrosternal pain, and odynophagia, especially if they have concomitant candidiasis (Samonis *et al.*, 1998). Given that endoscopy for direct identification may be problematic due to severe thrombocytopenia, esophageal candidiasis is often a clinical diagnosis (Pappas *et al.*, 2016). Treatment is longer, compared with oropharyngeal candidiasis, extending to 14–21 days. Therapy consists of fluconazole 200–400 mg (3–6 mg/kg) daily, with parenteral echinocandins, such as caspofungin, being an option for those patients who fail to tolerate, or fail therapy with, fluconazole (Pappas *et al.*, 2016).

Urinary tract infections with *Candida* species are typically associated with device infection, with Foley catheters and nephrostomy tubes serving as a nidus of these infections. In many cancer patients, these organisms may be associated with colonization of plastic surfaces and do not require treatment. In patients with neutropenic fever, however, candiduria may suggest occult disseminated candidiasis. Whether reflecting infection or colonization, an important first step is removal, if possible, or exchange of infected devices, such as nephrostomy tubes and Foley catheters (Pappas *et al.*, 2016). The most recent guidelines for management of candidiasis recommend 14 days of therapy with fluconazole 400 mg (approximately 6 mg/kg) daily. If a resistant *Candida* species is known or suspected, treatment may be changed to IV amphotericin B formulations, or amphotericin B bladder irrigation (Pappas *et al.*, 2016).

Invasive candidiasis, in contrast to superficial candidiasis, is a systemic infection and always requires systemic antifungal treatment. The infection still is associated with high mortality in cancer patients. A cohort study from Europe pointed to a 12 week crude

overall mortality in cancer patients of 49% (Cornely *et al.*, 2015). Historically, *Candida albicans* was the most common species associated with cancer, particularly in patients with less than 7 days of exposure to antifungals (Kullberg and Arendrup, 2015). However, in the era of widespread and prolonged antifungal prophylaxis, breakthrough candidemia with *Candida glabrata* or *Candida krusei* has been increasingly reported (Kullberg and Arendrup, 2015). *Candida parapsilosis* is associated with central venous catheter (CVC) infections (Horn *et al.*, 2009), but has also been noted, along with *Candida krusei*, in breakthrough infections in patients receiving micafungin for prophylaxis (Yacoub *et al.*, 2016). Candidemia is the most common manifestation of invasive candidiasis, with disseminated or single organ candidiasis now very rare, given the frequent use of prophylaxis for at-risk patients.

Diagnosis of invasive candidiasis routinely relies on blood culture, but given that cultures are negative in approximately 50% of cases of invasive candidiasis, non-culture based approaches have been developed (Pappas *et al.*, 2016; Clancy and Nguyen, 2018; Clancy *et al.*, 2018). These evolving tools include detection of 1,3-beta-D-glucan, T2 *Candida*, mannan antigen and mannan antibody, and various PCR-based approaches (Pappas *et al.*, 2016; Clancy and Nguyen, 2018). These molecular assays have a sensitivity ranging from 58% to 91% and specificity 80%–98% (Johnson *et al.*, 2020). Concerns with the molecular approaches include cross-reactivity with other organisms that result in poor specificity, variable sensitivity, and concern that PCR testing, in particular, may identify organisms that are no longer viable. Therefore, blood culture remains the “gold standard” for diagnosis of invasive candidiasis.

Treatment of invasive candidiasis requires knowledge of the local epidemiology, as the frequency and resistance profile of *Candida* species vary in different centers, and the prior exposure of the particular patient to antifungals. In addition to appropriate selection of antifungals, various other elements are important in reducing mortality in patients with candidemia (Farmakiotis *et al.*, 2015). These elements have been developed into recommended bundles of care (Mejia-Chew *et al.*, 2019; Johnson *et al.*, 2020). Bundle elements that are associated with lower mortality include central line removal, echocardiography to examine for evidence of endocarditis (especially in patients with persistent candidemia), ophthalmologic examination, and longer duration of antifungal therapy (Mejia-Chew *et al.*, 2019). In neutropenic cancer patients, some elements of the bundle might be different. For example, the yield of ophthalmologic examination is considered very low in neutropenic patients, until at least one week after neutrophil recovery (Table 1) (Pappas *et al.*, 2016; Breazzano *et al.*, 2019). Risk factors associated with the rare complication of candidemia, *Candida* endocarditis, include prosthetic heart valves and presence of CVCs (Pappas *et al.*, 2016). Similarly, a recent study, however, showed that hematologic malignancy was associated with decreased risk for *Candida* endocarditis (aOR 0.09 [95% CI, 0.04–0.69]) (Foong *et al.*, 2020). This finding on multivariate logistic regression was attributed to thrombocytopenia, which reduces the formation of the fibrin-platelet complex and subsequent formation of valvular vegetations. Another proposed explanation for the low frequency of *Candida* endocarditis is that patients with hematologic malignancy are more aggressively monitored and treated, resulting in earlier identification and treatment of candidemia (Foong *et al.*, 2020).

Candida species identification and possibly in vitro susceptibility inform the selection of appropriate antifungal agents. Classes of antifungal agents used to treat invasive candidiasis include azoles (e.g., fluconazole, voriconazole), echinocandins (e.g., caspofungin), and polyenes (e.g., amphotericin B formulations) (Table 2) (Pappas *et al.*, 2016). If patients are stable clinically, without prior exposure to azole therapy, fluconazole is the 1st line agent recommended for treatment of invasive candidiasis (Pappas *et al.*, 2016). If patients are critically ill or neutropenic, echinocandins are recommended (Table 1) (Pappas *et al.*, 2016). Amphotericin B formulations are recommended for treatment of *Candida glabrata* (2nd line treatment to an echinocandin), *Candida parapsilosis* (2nd line treatment), and *Candida krusei*, with use limited due to nephrotoxicity (Pappas *et al.*, 2016). Several conundrums in treatment of candidiasis in neutropenic cancer patients exist (Colombo *et al.*, 2020).

Aspergillus spp. are the most common causes of invasive mold infections in cancer patients, affecting those with impaired immune systems, particularly those with hematologic malignancies. Similar to the endemic fungi, these organisms are inhaled, with conidia migrating to the distal alveolar space, where they germinate. At these sites, the immune system responds, with mononuclear cells and polymorphonuclear leukocytes attacking these spores as they germinate into hyphae. *Aspergillus* spp. are angioinvasive, occasionally resulting in catastrophic hemorrhagic episodes. The angioinvasive nature of *Aspergillus* spp. can be appreciated by tissue injury in the lungs seen on CT chest. A recent study suggested that enhanced CT imaging, utilizing angiography, may be particularly helpful in identifying infection by angioinvasive molds (Stanzani *et al.*, 2019a). Aspergillosis also affects sinuses, with acute sinusitis occurring in 15%–20% of neutropenic patients (Kosmidis and Denning, 2015; Andes *et al.*, 2016). In fact, sinus discharge with headache and facial swelling and ocular pain associated with sinus infection may be the initial clue to diagnosis of invasive aspergillosis (Fung *et al.*, 2019).

Risk factors for invasive aspergillosis include prolonged and significant cytopenias, high dose corticosteroids and active hematologic malignancy. Recent reports of invasive aspergillosis after respiratory viral infection, however, suggest a need for vigilance in less immunocompromised cancer patients with these viral infections. In a recent multicenter study, 19% of influenza patients admitted to the ICU were diagnosed with pulmonary aspergillosis (Schauwvlieghe *et al.*, 2018). In the midst of the SARS-CoV-2 pandemic, up to 27% of patients admitted to an ICU and mechanically ventilated were diagnosed with probable COVID-19 associated pulmonary aspergillosis (CAPA) (Bartoletti *et al.*, 2020). Suboptimal diagnostics make it difficult to define the role of SARS-CoV-2 infection in increasing risk for pulmonary aspergillosis, since SARS-CoV-2 patients do not typically undergo bronchoscopy with bronchoalveolar lavage (BAL).

The diagnosis of invasive aspergillosis infection relies on a combination of clinical suspicion, assessment of radiologic abnormalities on chest and sinus CT, culture and cytology from respiratory, sinus, or other specimens, β -D-glucan, and serum galactomannan (Marr *et al.*, 2004; Andes *et al.*, 2016). Other mold infections of the lung may appear similar, with a single center study suggesting that invasive pulmonary aspergillosis, in contrast with mucormycosis, is less likely to exhibit less than

Table 2 Antifungal characteristics

Drug	Spectrum of activity	Daily dose	Route	Side effects
D-AMB	Broad yeasts, molds	1–1.5 mg/kg	IV only	Nephrotoxicity, hypokalemia, hypomagnesemia
Lipid AMB	Broad yeasts, molds	3–5 mg/kg	IV only	Nephrotoxicity < D-AMB, hypokalemia, hypomagnesemia
Fluconazole	Yeasts, including <i>Cryptococcus</i>	400–800 mg (6 mg/kg/day)	IV, Oral	Headache, rare hepatotoxicity
Isavuconazole	Broad yeasts, molds, not <i>Fusarium</i>	372 mg	IV, Oral	Diarrhea, headache
Itraconazole IV	Endemic molds, some <i>Candida</i> spp.	200 mg	IV/oral	Nausea, vomiting, headache, rare hepatotoxicity, drug interactions (oral with osmotic diarrhea)
SUBA-itraconazole	Endemic molds, <i>Aspergillus</i> spp., some <i>Candida</i> spp.	130 mg (130 mg q12hrs Aspergillois)	Oral	Nausea, vomiting, headache, rare hepatotoxicity, pulmonary edema, drug interactions
Posaconazole tabs	Broad yeasts, molds	300 mg	Oral	Nausea, vomiting, hepatotoxicity
Posaconazole IV	Broad yeasts, molds	300 mg	IV	Nausea, vomiting, hepatotoxicity
Posaconazole (susp)	Broad yeasts, molds	200 mg every 6 h	Oral	Nausea, vomiting, hepatotoxicity
Voriconazole IV	Yeasts, molds, not <i>Mucorales</i> spp.	4 mg/kg every 12 h	IV	Visual abnormalities, rash, nausea, vomiting, headache, hepatotoxicity, drug interactions, skin cancer, bone health issues, neuropathy
Voriconazole tabs	Yeasts, molds, not <i>Mucorales</i> spp.	200 mg every 12 h (>40 kg)	Oral	Visual abnormalities, rash, nausea, vomiting, headache, hepatotoxicity, drug interactions
Caspofungin	Broad yeasts, <i>Aspergillus</i> , not endemic, other molds	50 mg	IV	Fever, nausea, flushing; rash; some drug interactions; phlebitis
Micafungin	Broad yeasts, <i>Aspergillus</i> , not endemic, other molds	150 mg	IV	Fever, nausea, flushing; rash; some drug interactions; phlebitis
Anidulafungin	Broad yeasts, <i>Aspergillus</i> , not endemic, other molds	100 mg	IV	Fever, nausea, flushing; rash; some drug interactions; phlebitis

Note: D-AMB, amphotericin B deoxycholate; IV, intravenous; susp, suspension; tabs, tablets.

10 pulmonary nodules or pleural effusion (Chamilos *et al.*, 2005). Given the challenge of identifying specific causes of invasive pulmonary mold infections, early bronchoscopy significantly increases likelihood of identifying a specific mold. Bronchoscopy performed less than 4 days after presentation increases the yield from as low as 22% to as high as 78% (Shannon *et al.*, 2010).

Treatment of aspergillosis consists of various options. Mold active triazoles, such as voriconazole, isavuconazole, and posaconazole are the mainstay of treatment, while lipid formulations of amphotericin B are considered second line in view of nephrotoxicity (Table 1). Echinocandins have a limited role as monotherapy for treatment of IA (Table 1). Mortality depends on the resolution of neutropenia with invasive aspergillosis, with mortality of 45% resulting from treatment with either leading option of voriconazole or isavuconazole, in the setting of persistent neutropenia (Kontoyiannis *et al.*, 2018). General principles of management of invasive aspergillosis include efforts at early diagnosis, attention to drug-drug interactions, therapeutic drug monitoring, discontinuation of unnecessary immunosuppressive medications, and appropriate follow up to assure resolution of signs and symptoms attributable to infection, to include imaging and/or biomarkers (Patterson *et al.*, 2016; Fernandez-Cruz *et al.*, 2020).

Cryptococci are encapsulated yeasts that emerged as important pathogens affecting HIV patients in the 1980s. Among the Cryptococci, *Cryptococcus neoformans* is the most common species infecting humans (Perfect *et al.*, 2010). This organism is found in pigeon secretions, and when inhaled, it could cause disease in patients with lymphopenia or lymphocyte dysfunction, associated with chemotherapy and corticosteroids (Kontoyiannis *et al.*, 2001). Ibrutinib and other kinase inhibitors, as mentioned earlier, have been associated with excess risk for cryptococcosis, as well as other invasive fungal infections (Chamilos *et al.*, 2018). Patients may have various presentations of cryptococcal infection, including pneumonia, central nervous system (CNS) infection, and disseminated cryptococcosis. Diagnosis of pneumonia is confirmed by fine-needle aspiration, BAL, and/or open lung biopsy, with 90% yield on culture, in a single cancer center study (Kontoyiannis *et al.*, 2001). CNS infection may manifest with fever and headache, dizziness, somnolence, confusion, and obtundation (Perfect *et al.*, 2010). Painless skin lesions are often a visible manifestation of disseminated cryptococcosis, which also affect the liver, prostate, eyes, and bone (Perfect *et al.*, 2010). Biopsy of the lesions with fungal culture may identify these yeasts, but serum cryptococcal antigen has a sensitivity and specificity over 90% for invasive disease (Perfect *et al.*, 2010).

Treatment of cryptococcal infection depends on the affected site (Table 1). In addition to patient with CNS manifestations of cryptococcal infection, other high risk groups for CNS infection should undergo routine diagnostic lumbar puncture. For example, patients with proven disseminated *Cryptococcus*, severe pulmonary cryptococcal infection, HIV, and otherwise immunocompromised hosts with proven infection, should undergo routine lumbar puncture. For patients with severe pulmonary or CNS infection, amphotericin B formulations (e.g., Liposomal amphotericin B 5 mg/kg/day) are typically combined with 5-flucytosine, as an induction therapy. 5-flucytosine levels should be measured, to avoid toxicity. Patients with suspicion of CNS infection

should undergo lumbar puncture with measurement of baseline CSF pressure. If the CSF pressure is ≥ 25 cm H₂O, then the patient should undergo daily lumbar puncture until the CSF pressure and symptoms remain stable for more than 2 days (Perfect *et al.*, 2010). After establishing control of infection, typically after at least 2 weeks, there is a transition to consolidation therapy with fluconazole 6 mg/kg/day, to be followed by maintenance therapy 200 mg daily for a period of at least 6–12 months. Patients with mild to moderate pulmonary infection may be treated with fluconazole 6 mg/kg/day alone, not requiring the more toxic amphotericin B formulation with 5-flucytosine (Perfect *et al.*, 2010). Given the complexity of management, infectious diseases consultation has been shown to reduce mortality (Spec *et al.*, 2017).

Fusarium spp. are opportunistic molds derived from air and soil, causing a spectrum of infections, from superficial skin and keratitis, due to direct inoculation, to locally invasive disease following trauma, to severe sino-pulmonary or disseminated infection. The *Fusarium solani* complex of species is associated with half of cases (Campo *et al.*, 2010). The invasive form of these infections affects profoundly immunosuppressed patients with uncontrolled hematologic malignancy or stem cell transplant (Campo *et al.*, 2010). These cases are often associated with fungemia, with blood cultures positive in 50%–70% of cases (Lionakis and Kontoyiannis, 2004). In these neutropenic patients, dissemination may occur as often as 75% of cases, classically with papules with central necrosis or eschar (Bodey *et al.*, 2002). Unfortunately, outcomes remain poor, with mortality ranging from 50% to 94% (Lionakis and Kontoyiannis, 2004; Campo *et al.*, 2010; Lamoth and Kontoyiannis, 2019), since the underlying disease is the major driver of mortality. Treatment is challenging, with limited effectiveness of various agents, with voriconazole and posaconazole used as alternatives to amphotericin B formulations, depending on the *Fusarium* spp. (Tables 1 and 2).

Mucormycosis is caused by various *Mucorales* spp., with exposure by inhalation of these mold spores from the environment. This mold, similar to *Aspergillus* spp., is highly angioinvasive, resulting in thrombosis and tissue infarction. Cancer patients affected include those with acute leukemia and HSCT recipients, but may also include those with high corticosteroid use, diabetic ketoacidosis or iron overload (Kontoyiannis and Lewis, 2014). Prior exposure to voriconazole is also a significant risk factor for mucormycosis (Chamilos *et al.*, 2005). Mucormycosis in cancer patients typically presents as sinusitis, sinopulmonary disease, less often as rhino-orbital infection (typically seen in patients with diabetic ketoacidosis) (Roden *et al.*, 2005). Disseminated infection, manifesting as cutaneous, GI, or other single organ mucormycosis, can be encountered in severely immunocompromised cancer patients. As with *Fusarium* spp., treatment can be difficult, with an overall mortality rate of 44%–71% (Kontoyiannis and Lewis, 2014), although neutropenic patients with disseminated disease have an abysmal 90% mortality rate, especially if treatment is delayed (Chamilos *et al.*, 2008). Therapy for mucormycosis consist of amphotericin B lipid formulations, with posaconazole and isavuconazole used for stepdown or intolerance to amphotericin B formulations in less severe disease (Table 1) (Roden *et al.*, 2005; Spellberg *et al.*, 2009; Miceli and Kauffman, 2015).

Endemic Fungal Infections

In the USA, there are three common endemic fungal infections, which are caused by dimorphic fungi. These include coccidioidomycosis, histoplasmosis, and blastomycosis, with a wide geographic distribution (Fig. 1). The organisms are dimorphic fungi that share inhalation as the most common mode of acquisition of infection, but differ in their geography and associated climate. These endemic fungal infections share the predisposition to cause pulmonary disease, with lung nodules that may at times be confused with malignancy (Kontoyiannis, 2017). In patients with known primary or metastatic lung disease, pulmonary imaging may show overall improvement of oncologic lung disease, but with development of new lung lesions. Given suspicion of cancer, patients undergo biopsy, with fungal organisms present on pathology, rather than the anticipated cancer. In such a scenario, cultures are often not sent, leaving pathologists with the challenge of attempting diagnosis based on morphology. Fungal antibody and/or urine antigen testing may also fail to reveal the endemic fungal infection, leaving healthcare providers with the task of selecting empiric treatment, based on limited information. In such cases, other features noted on careful history, examination, and assessment of available laboratory and radiologic data, help to identify the specific endemic mold infection.

Coccidioidomycosis, otherwise known as “Valley fever”, is a fungal infection associated with the inhalation of single celled arthroconidia, with a wide distribution in the southwest USA (Fig. 1) (Donovan *et al.*, 2019). The two species that cause disease in the USA are *Coccidioides immitis* and *Coccidioides posadasii* (Van Dyke *et al.*, 2019), with the distribution in the arid regions of the southwestern USA, although with endemic cases reported in Eastern Washington (Van Dyke *et al.*, 2019), as well as Mexico, Central and South America (Donovan *et al.*, 2019). Approximately 60% of the estimated 350,000 patients infected annually develop asymptomatic or mildly symptomatic infections (Donovan *et al.*, 2019; Van Dyke *et al.*, 2019). Some patients develop a syndrome suggestive of community-acquired pneumonia, with nonproductive cough, chest pain, and shortness of breath (Valdivia *et al.*, 2006).

Other patients develop more severe symptoms, including arthralgias, fever, night sweats, and weight loss, with dissemination to bones and joints, meninges, central nervous system (meningitis), and/or skin estimated to occur in <1% of patients (Galgiani *et al.*, 2016; Van Dyke *et al.*, 2019). Approximately 16% of patients with disseminated disease develop central nervous system infection (typically meningitis), which is almost universally fatal, if untreated. A recent study showed immunosuppression increased risk for dissemination, estimated to occur in 30%–50% of immunocompromised hosts, but only 13% of those in the study were cancer patients (Odio *et al.*, 2017). Diagnosis of coccidioidomycosis consists of biopsy with culture, serologic testing, antigen testing, and PCR (Nguyen *et al.*, 2013). On biopsy, a spherule may be seen, which contains endospores, recognized as consistent with coccidioidomycosis, if seen in this form.

Treatment of coccidioidomycosis depends on the presentation of the patient and risk factors (Galgiani *et al.*, 2016). Recent expert commentary suggested that treatment is not necessary for patients with self-limiting disease, stable observed manifestations of

Estimated areas with blastomycosis, coccidioidomycosis (Valley fever), and histoplasmosis in the United States

CS 313826-A January 02, 2020

Fig. 1 Geographic distribution of endemic fungal infections. Available at: <https://www.cdc.gov/nceid/dfwed/PDFs/fungal-factsheet-508c.pdf>.

disease, such as lung nodules, but noting that those with “major cellular immunodeficiency” are predisposed to progressive disease, so should proceed with treatment (Galgiani *et al.*, 2019). To reflect the challenge of the scenario of an immunosuppressed cancer patient with asymptomatic coccidioides lung nodules, the suggestion is to evaluate for occult extrapulmonary findings with PET/CT (Foerter *et al.*, 2016) and proceed with treatment trial with an oral azole (e.g., fluconazole) for 3 months, with close monitoring (Kontoyiannis, 2017). Depending on the risk for other mold infections, such as hematologic malignancy or allogeneic transplant, a more broad mold active agent, such as voriconazole or posaconazole may be considered (Table 2) (Kontoyiannis, 2017).

Histoplasmosis is classically seen in the Ohio and Mississippi River Valleys, in areas of high humidity and moderate temperature (Fig. 1). Patients with histoplasmosis may share a recent history of cave exploration (“spelunking”), work or live near chickens or birds, chop wood, live or frequent wooded areas, or be involved in construction, renovation, or cleaning of buildings with bird or rat droppings. Patients typically acquire this fungal infection by inhalation, with the formation of granulomatous lesions in the lung and other organs (Benedict *et al.*, 2019a). Patients predominantly have asymptomatic or self-limited infection, but one out of every two thousand patients develops chronic pulmonary infection, and some severely immunocompromised patients develop disseminated histoplasmosis. A recent surveillance study conducted by the CDC found a 67% hospitalization rate with 7% mortality (Armstrong *et al.*, 2018). A 2012 study that provided greater detail regarding immunocompromised patients showed a distribution of HIV (17%), diabetes mellitus (21%), and autoimmune diseases (10%), but only 7% of patients with hematologic malignancy or transplant (Benedict *et al.*, 2016).

Diagnosis of histoplasmosis, as with coccidioidomycosis, can be challenging. Epidemiology provides important initial clues, in patients with lung nodules. As with other fungal infections, the optimal approach is direct visualization of the fungus from tissue, ideally with culture to confirm the diagnosis. Chest imaging commonly demonstrates not only pulmonary nodules, but also mediastinal lymphadenopathy. A study of an enzyme immunoassay to detect IgG and IgM antibodies to optimize sensitivity in acute pulmonary histoplasmosis showed a combined sensitivity of 76.7% (Richer *et al.*, 2016). In the study, complement fixation showed 66.7% sensitivity and urine histoplasmosis antigen sensitivity of 53.8%, but increased to 76.7% when combined with serum antigen (Richer *et al.*, 2016). More recently developed tests include lateral flow and isothermal amplification assays (Sanguinetti *et al.*, 2019). A high index of suspicion is necessary to consider appropriate testing, with many options available for diagnosis.

Treatment is generally deferred in patients with incidental finding of an asymptomatic pulmonary nodule, but cancer type and underlying degree of immune deficiency are considered in assessing risk for progression without treatment. Treatment of

histoplasmosis depends on severity of infection, in addition to underlying immunocompromised status, with Amphotericin B formulations recommended for patients with severe pulmonary or disseminated infection (**Table 2**) (Wheat *et al.*, 2007). Itraconazole continues to be the recommended 1st line oral therapy, per guidelines (Wheat *et al.*, 2007), but other options include posaconazole, voriconazole, and isavuconazole (**Table 2**) (Wheat *et al.*, 2016). In addition, SUBA-itraconazole is a new formulation of itraconazole with significantly improved bioavailability (**Table 2**) (Abuhelwa *et al.*, 2015). Fluconazole is another option, but has a high failure rate, so it is generally avoided (Wheat *et al.*, 2007; Wheat *et al.*, 2016). Treatment should be individualized, with multiple factors considered, including underlying immunodeficiency from cancer and from the treatment for cancer, comorbidities, underlying lung disease, potential for drug-drug interactions with ongoing cancer treatment, absorption, compliance, and feasibility for follow up.

Blastomycosis is the 3rd most endemic invasive fungal infection, and can be encountered in both immunocompetent, and immunocompromised hosts, including cancer patients. As with histoplasmosis and coccidioidomycosis, blastomycosis is a dimorphic fungus present in soil, with conidia inhaled into the lungs, where they convert to yeast form. Similar to coccidioidomycosis and histoplasmosis, approximately 50% of patients develop subclinical infection, with up to 75% of cases remaining confined to the lungs (Castillo *et al.*, 2016). Blastomycosis shares a similar geographic distribution to histoplasmosis, with highest incidence in the Mississippi and Ohio River valleys, but is seen further to the north, particularly the Great Lakes area into Canada, and the southeast (**Fig. 1**).

Blastomycosis may present as an incidental finding on chest imaging during the initial diagnostic workup for cancer or during radiologic surveillance of cancer patients. Patients may also develop fever, chills, cough, and occasionally hemoptysis. A study from Indiana showed a 12% mortality with diabetes mellitus, multilobar pneumonia, and immunosuppression (16% of the cohort, with 56% of those either with solid or hematologic malignancy) associated with increased risk of ICU admission (Azar *et al.*, 2015).

Diagnosis of blastomycosis consists of direct visualization of the organism on biopsy of skin or pulmonary nodules and yield of culture from bronchoscopic specimens has been reported as high as 92% (Martynowicz and Prakash, 2002). A differentiating feature of blastomycosis is that rather than formation of pulmonary nodules, lung consolidation is more common (McBride *et al.*, 2017). An antigen assay that targets the galactomannan component of the cell wall may be used on urine, serum, cerebrospinal fluid, and bronchoalveolar lavage specimens. Sensitivity in urine is 76%–93%, with specificity of 79%, but there is cross-reactivity with other endemic fungi such as histoplasmosis and coccidioidomycosis. Of note, the antigen concentration can be used to monitor response to treatment (Frost and Novicki, 2015).

Guidelines for the treatment of blastomycosis exist (Chapman *et al.*, 2008). The decision to treat and the selection of agent depends on the site of infection, as well as the severity of immunosuppression of the host. In contrast to other endemic fungal infections, the recommendation is to routinely proceed with treatment, except in cases with significant clinical improvement before confirmation of the diagnosis (Chapman *et al.*, 2008). Given the concern for development of extrapulmonary infection, particularly in immunocompromised hosts, the preference is to proceed with oral itraconazole, based on available guidelines for asymptomatic cases, as well as those with mild to moderate pulmonary infection or disseminated infection (Chapman *et al.*, 2008; McBride *et al.*, 2017). For patients with moderately severe disease, the recommendation is to start with a lipid formulation of amphotericin B. Patients who are immunocompromised, as well as those who have CNS disease, should also be given amphotericin B formulations, regardless of manifestation of infection. The duration of the amphotericin B-based intravenous regimen, is typically limited to 1–2 weeks, or until the patient improves clinically and/or radiologically. Itraconazole poses challenges of absorption and toxicity. The new formulation of itraconazole, SUBA-itraconazole, addresses the challenge of absorption, dramatically increasing bioavailability (**Table 2**) (Abuhelwa *et al.*, 2015). Newer antifungals, such as voriconazole, posaconazole, and isavuconazole (**Table 2**), however, exhibit activity against blastomycosis. These medications have less drug-drug interactions than itraconazole, and achieve target concentrations with less difficulty, particularly in cancer patients, in whom drug-drug interactions and requirements for absorption of eating or drinking certain foods are challenging (McBride *et al.*, 2017).

In summary, the endemic mycoses, including coccidioidomycosis, histoplasmosis, and blastomycosis, often manifest with lung nodules and constitutional symptoms, which may initially be mistaken for lung cancer or lung metastases of another primary cancer. All these endemic mycoses result from environmental exposures to spores, which can transform after inhalation or inoculation into different forms. Endemic mycoses are typically associated with mild disease, but may cause severe disease in both immunocompromised hosts with cancer. A high index of suspicion and knowledge of epidemiological range of these organisms help to guide diagnosis. Once the diagnosis is established, careful consideration is essential, beginning with “staging” of infection, to determine if dissemination has occurred from the lungs and the extent of the seeding of infection. This “staging” of infection will impact the selection of the appropriate antifungal, route of therapy, and duration of antifungal therapy.

Prevention of Fungal Infections in Cancer Patients

The prevention of fungal infections in cancer patients requires a baseline assessment of risk, based on knowledge of host factors as well as the impact of cancer treatment on immune responses to fungal infection. Among recommendations to prevent fungal infection in cancer patients, an important note is to consider environmental exposures (Ariza-Heredia and Kontoyiannis, 2014). This encompasses exposure to soil excavation, construction, landscaping, farming, and gardening. These activities may lead to inhalation of mold spores or direct inoculation of the organisms into the skin. Other environmental exposures of concern include

^a Primary prophylaxis during initial remission-induction chemotherapy; ^b Prophylaxis during re-induction for relapsed leukemia, prolonged corticosteroid treatment for graft-versus-host disease; ^c CT pulmonary angiography used in some centers to identify angioinvasive process (vessel occlusion sign) inside nodular infiltrates or consolidations; highly suggestive of invasive mold disease and not affected by antifungal prophylaxis; ^d If suggestive signs of involvement; ^e PCR test for *Aspergillus* spp. with or without detection of L98H, tandem repeat 34, T289A, and Y1212F triazole resistance mutations. Not approved in U.S. or available in most centers; ^f Susceptibility testing is not available in many centers and clinical breakpoints are not established for non-*Aspergillus* molds; ^g although ISA and POS achieve lower concentrations in the CNS compared to VRC, it is unclear whether more CNS bIMIs are seen with the first 2 triazoles; ^{**} echinocandins are considered to achieve suboptimal CNS concentrations; * starting with an IV formulation is favored, especially for VRC. Less convincing data exist that IV POS results in better levels than POS DR, tablets, no data exist regarding ISA. AMB, amphotericin B; CNS, central nervous system; CT, computed tomography; ISA, isavuconazole; IV, intravenous; PCR, polymerase chain reaction; POS, posaconazole; PK, pharmacokinetic; TDM, therapeutic drug monitoring; VRC, voriconazole.

Fig. 2 Management of breakthrough fungal infections.

smoking, especially marijuana, and consumption of certain foods, particularly for patients who are neutropenic. These include fresh fruits, smoked foods, moldy cheeses, and spices and nuts that can be contaminated with fungi.

In patients with cancers, such as ALL, MDS, AML, prophylaxis with antifungals is often recommended to prevent fungal infection. Prophylaxis with fluconazole is associated with high risk of breakthrough mold infection (**Fig. 2**) (Halpern *et al.*, 2015; Lionakis *et al.*, 2018). Echinocandins (e.g., micafungin) provide activity against *Candida* spp., as well as some *Aspergillus* spp. isolates, but do not provide protection against non-*Aspergillus* molds, such as *Fusarium* or *Mucorales* spp., and are not favored for prophylaxis in very high risk patients (**Table 1**) (Gomes *et al.*, 2014). Voriconazole provides excellent activity against *Candida* spp., *Aspergillus* spp., and *Fusarium* spp. (**Table 1**) (Halpern *et al.*, 2015), but is associated with excess cases of infections with *Mucorales* species (**Fig. 2**) (Chamilos *et al.*, 2005; Lionakis *et al.*, 2018). Posaconazole has very broad activity against yeasts and many mold isolates, including *Mucorales* species (**Table 1**), showing an impact on survival in patients undergoing induction therapy for AML (Halpern *et al.*, 2015). The class of polyenes (e.g., amphotericin B) also has broad activity, but exhibits unacceptably high rates of nephrotoxicity and is reserved for treatment, not prophylaxis.

Mycobiome

In contrast to the study of the microbiome, the “mycobiome” has not been well characterized in cancer patients. Increasing work, however shows the impact of cancer treatment on the mycobiome and the impact of the mycobiome on cancer (Aykut *et al.*, 2019; Robinson *et al.*, 2020). In a recently described cohort of patients with acute myelogenous leukemia (AML) undergoing remission induction chemotherapy (RIC), the change in mycobiome diversity did not appear to be impacted by antibacterial therapy, but was decreased in patient undergoing high-intensity RIC. In addition, the relative abundance of *Fusarium* species increased with amphotericin B exposure (Robinson *et al.*, 2020). Of interest, relative abundance of particular fungi at particular time points during RIC was associated with risk of bacterial infection, adding to the evidence that there are interkingdom interactions between fungi and bacteria that likely have an impact on patient outcomes (Robinson *et al.*, 2020). A fascinating, yet concerning, finding is that an approach to addressing refractory *Clostridioides difficile* infection, using fecal microbiota transplantation (FMT), is negatively impacted by *Candida* colonization of the GI tract (Galloway-Pena and Kontoyiannis, 2020). This is attributed to the impact of *Candida* colonization on attempts to reconstitute gut flora.

A change in the mycobiome not only impacts the risk for bacterial infection, but a recent study suggests that fungi may migrate from the intestinal lumen to the pancreas in an animal model of pancreatic ductal adenocarcinoma. This migration results in tumor growth driven by binding of the glycan surface of the cell wall to mannose-binding lectin, driving the complement cascade to “accelerated” oncogenesis (Aykut *et al.*, 2019). Of interest, the oncogenesis, even in the setting of inflammation, was not driven by all fungal species, but specifically by *Malassezia* species (Aykut *et al.*, 2019). Similarly, changes in the mycobiome, with increasing *Malassezia* and decreased *Saccharomyces* species, have also been associated with colorectal cancer (Galloway-Pena and Kontoyiannis, 2020).

Future Directions

In summary, fungi are a diverse group of organisms that may affect cancer patients with manifestations, ranging from superficial skin infection to pneumonia with disseminated disease. Some virulent fungi, such as *Histoplasma*, infect patients with intact immune systems. However, most fungal infections in cancer patients are caused by opportunistic fungi, such as *Candida* or *Aspergillus* spp., which are typically harmless colonizers on mucosal surfaces in immunocompetent hosts. The impact of new cancer treatments, including immunomodulatory therapies, on the risk of fungal infection is an exciting area of study (Chamilos *et al.*, 2018; Abers and Lionakis, 2020). Novel diagnostics and new antifungals with novel mechanisms of action are being developed, with emphasis on varied routes of administration and decreased drug-drug interactions.

With improved outcomes of cancer treatment resulting in a 27% decrease in cancer death rate from 1991 to 2016, the role of fungal infection will become increasingly important not only in patients undergoing active cancer treatment, but also in cancer survivors. The number of cancer survivors in the USA is expected to grow from 16.9 million cancer survivors on 2019 to a projected 22.1 million by 2030 (Siegel *et al.*, 2019). An improved understanding of how fungi interact with the host and other organisms will guide optimal outcomes for these often underappreciated organisms in cancer care.

Fungal Infections in the Setting of Biological Therapies (in the Non-Transplant Host)

Michail S Lionakis, National Institute of Allergy and Infectious Diseases, National Institutes of Health, United States

© 2021 Elsevier Inc. All rights reserved.

Introduction

In the past few decades, the AIDS epidemic and major advances in modern medicine associated with the introduction of a variety of immunomodulatory and chemotherapeutic interventions for the treatment of autoimmune and neoplastic diseases and the expansion of the clinical indications and applications of hematopoietic stem cell transplantation (HSCT) and solid organ transplantation (SOT) have markedly expanded the populations of individuals who are at risk for development of mucosal and/or invasive fungal infections (IFIs) (Brown *et al.*, 2012; Lionakis *et al.*, 2017b; Lionakis and Levitz, 2018). Indeed, opportunistic fungal infections have emerged as significant causes of morbidity and mortality in acutely ill and immunosuppressed patients. For example, invasive candidiasis is among the three most common causes of nosocomial bloodstream infections in intensive care units in the United States with mortality that exceeds 30%–40% despite administration of antifungal therapy (Magill *et al.*, 2014, 2018; Strollo *et al.*, 2016). The recent emergence of drug-resistant *Candida* species including *Candida glabrata* and *Candida auris* raises significant public health concerns (Alexander *et al.*, 2013; Vallabhaneni *et al.*, 2019). *Candida* species also cause mucosal infections, which occur in the form of oral and esophageal disease in the vast majority of AIDS patients when they are not treated with antiretroviral therapy and in the form of recurrent vulvovaginal candidiasis in over 100 million women annually worldwide (Denning *et al.*, 2018). Invasive pulmonary aspergillosis (IPA) is a leading cause of infection-related mortality in neutropenic and/or corticosteroid-treated patients with hematological malignancies and HSCT (Lionakis and Kontoyiannis, 2003; Segal, 2009). Cryptococcosis is a major opportunistic infection in AIDS patients that is responsible for ~200,000 deaths per year worldwide (Rajasingham *et al.*, 2017), while *Pneumocystis jirovecii* pneumonia (PJP), the most common opportunistic respiratory infection in AIDS patients (Siegel *et al.*, 2016), is estimated to cause >400,000 life-threatening infections per year worldwide (Brown *et al.*, 2012).

Besides these “traditional” risk factors that predispose to opportunistic fungal disease, a recent surge in the discovery and clinical use of mechanism-based biological therapies in the form of either monoclonal antibodies (mAbs) (and associated biosimilars) or small molecule kinase inhibitors (SMKIs) has revolutionized the management of neoplastic and autoimmune disorders (Grilo and Mantalaris, 2019; Wu *et al.*, 2016). The biologic agent that changed everything in the landscape of clinical applications for such therapies is the SMKI imatinib, which in the early 2000s showed remarkable efficacy and safety for the treatment of Philadelphia chromosome-positive chronic myelogenous leukemia and gastrointestinal stromal tumors via inhibition of the BCR-ABL tyrosine kinase and the KIT receptor tyrosine kinase, respectively (Demetri *et al.*, 2002; Kantarjian *et al.*, 2002; Longo, 2017).

Since then, an unprecedented rate of discovery and clinical use of biological therapies that inhibit a variety of extracellular and intracellular immune-related molecules has underscored the critical contribution of some of these targeted molecules and pathways in mounting effective innate and adaptive antifungal immune responses in humans (Chamilos *et al.*, 2018; Zarakas *et al.*, 2019). Indeed, opportunistic mucosal and/or systemic fungal infections have emerged in the setting of treatment with some of these biological therapies (Chamilos *et al.*, 2018; Ghez *et al.*, 2018; Lionakis *et al.*, 2017a; Varughese *et al.*, 2018). In this chapter, I highlight key biological therapies, both mAbs and SMKIs, that have been associated with an increased risk of opportunistic fungal disease in patients with malignant and autoimmune diseases. The risk of fungal disease associated with such biological therapies in the context of transplantation, either HSCT or SOT, is beyond the scope of this chapter. Before outlining key biological therapies as novel risk factors for human fungal disease, I briefly summarize the cellular and molecular immune factors that are required for effective host defense against mucosal and/or invasive infection by different pathogenic fungi, as this outline will provide a useful roadmap for understanding the pathogenesis of opportunistic fungal diseases that arise in the context of biological therapies.

Immune Cells and Signaling Pathways That Promote Fungus-Specific Host Defense

The immune cell subsets and signaling pathways that mediate protective antifungal immunity vary greatly depending on the infecting fungus and anatomical site (Lionakis *et al.*, 2017b; Lionakis and Levitz, 2018). Hence, understanding the cellular and molecular basis of fungus-specific and tissue-specific host defense is critical for recognizing and predicting the fungal infection risk conferred by biological therapies that target the corresponding immune cells and signaling pathways.

Mucosal Candidiasis

Lymphoid cells and IL-17 receptor (IL-17R) signaling play a crucial role in protection against oropharyngeal candidiasis in mice and humans. Studies in mice have shown that the IL-17 cytokines IL-17A and IL-17F are rapidly produced at the mucosal surface upon *Candida* infection by proliferating $\alpha\beta$ T cells termed natural Th17 cells, by $\gamma\delta$ T cells, and by innate lymphoid cells type-3 (ILC3) (Conti *et al.*, 2009, 2014, 2016; Trautwein-Weidner *et al.*, 2015; Gladiator *et al.*, 2013). IL-17A and IL-17F then bind to IL-17RA and IL-17RC on the epithelial cell surface within the keratin 13-expressing suprabasal epithelial layer and drive the production of antifungal antimicrobial peptides such as S100a8, S100a9, β -defensin 1 and β -defensin 3 that are thought to curtail

Candida invasion within the mucosa. Concordant to these mouse findings, patients with inherited immune deficiencies caused by mutations in *IL17F*, its receptors *IL17RA* and *IL17RC*, and the IL-17R adapter protein ACT1 (which is encoded by *TRAF3IP2*) are susceptible to chronic mucocutaneous candidiasis (CMC), which is characterized clinically by recurrent, treatment-refractory, and/or severe *Candida* infections that involve mucocutaneous anatomical sites (i.e., oral cavity, esophagus, vagina, skin, nails) but without fungal systemic dissemination (Boisson *et al.*, 2013; Puel *et al.*, 2011, 2012; Levy *et al.*, 2016; Ling *et al.*, 2015). Similarly, several other monogenic disorders that manifest with CMC such as those caused by mutations in *STAT1*, *STAT3*, *AIRE*, *RORC*, *IRF8*, *DOCK8*, or *CARD9* feature various defects in IL-17R-associated immune responses (Constantine and Lionakis, 2019; Corvilain *et al.*, 2018; Hambleton *et al.*, 2011; Lionakis *et al.*, 2014; Liu *et al.*, 2011; Milner *et al.*, 2008; Okada *et al.*, 2015; Puel *et al.*, 2010; van de Veerdonk *et al.*, 2011; Keles *et al.*, 2016; Kisand *et al.*, 2010).

IFIs by *Candida* and Inhaled Molds

Although lymphoid cells and IL-17R signaling critically promote immunity against *Candida* at the mucosal level, they are dispensable for host defense against invasive candidiasis (and invasive mold infections [IMIs]). Indeed, patients with AIDS are susceptible to mucosal candidiasis but are not at high risk for developing invasive candidiasis or IMIs.

Instead, protective immunity against invasive infections by *Candida* and inhaled molds relies on neutrophils and monocytes/macrophages, which traffic to the site of fungal infection in response to fungus-specific and tissue-specific molecular cues and become activated locally to exert direct fungal killing via both oxidative burst- and non-oxidative burst-dependent molecular mechanisms [reviewed in detail elsewhere (Lionakis and Levitz, 2018; Netea *et al.*, 2015)]. Indeed, patients with chemotherapy-induced profound and prolonged neutropenia and those with iatrogenic phagocyte defects associated with corticosteroid use are at high risk for developing invasive candidiasis and IMIs. In addition, defective phagocyte oxidative burst in patients with chronic granulomatous disease (CGD) significantly increases the risk of invasive mold (and to a lesser extent *Candida*) infections (Lionakis, 2012; Winkelstein *et al.*, 2000). In addition, defective neutrophil recruitment and non-oxidative burst-mediated fungal killing in the setting of inherited deficiency of the C-type lectin receptor (CLR) adapter protein CARD9 (Caspase recruitment domain-containing protein 9) drives susceptibility to invasive candidiasis and IMIs with a propensity to involve the central nervous system (CNS) (Drewniak *et al.*, 2013; Drummond *et al.*, 2015, 2019; Rieber *et al.*, 2016; Corvilain *et al.*, 2018; Lanternier *et al.*, 2015b).

Infections by Intracellular Fungi (*Cryptococcus*, Endemic Dimorphic Fungi and PJP)

Effective immunity against AIDS-associated intracellular fungal pathogens such as *Cryptococcus* species, PJP, and endemic dimorphic fungi (i.e., *Histoplasma*, *Coccidioides*, *Blastomyces*, *Talaromyces* species) depends on establishment of an efficient cross-talk between IFN- γ -producing lymphocytes (i.e., CD4 T cells and NK cells) and activated mononuclear phagocytes (Lionakis *et al.*, 2014; Rosain *et al.*, 2019). Specifically, upon engulfment of fungal elements, mononuclear phagocytes produce IL-12, which binds on its receptor (IL-12R, consisting of $\beta 1$ and $\beta 2$ subunits) on the surface of CD4 T and NK cells. IL-12 engagement in these lymphocytes activates STAT4 that facilitates the production of IFN- γ , which binds on its receptor (IFN- γ R, consisting of $\beta 1$ and $\beta 2$ subunits) on the surface of macrophages. IFN- γ R engagement activates JAK1-JAK2-STAT1 signaling, which leads to STAT1 nuclear translocation and induction of the transcription of IFN- γ -related genes, which result in intracellular fungal killing (Milner and Holland, 2013; Rosain *et al.*, 2019; O'Shea *et al.*, 2013). Besides IFN- γ , two other Th1-polarized cytokines, TNF- α and GM-CSF, are also critically important in inducing an effective lymphocyte-macrophage cross-talk that drives intracellular fungal clearance (Lionakis and Levitz, 2018). In agreement with the role of the aforementioned IFN- γ /IL-12 signaling cascade in host defense against intracellular fungi, patients with inherited immune deficiencies caused by mutations in *IL12*, *IL12RB1*, *IL12RB2*, *STAT4*, *IFNGR1*, *IFNGR2* and *STAT1* and individuals with acquired immune deficiencies caused by neutralizing autoantibodies against IFN- γ , IL-12 or GM-CSF manifest with disseminated infections by intracellular fungal (and mycobacterial) pathogens (Browne *et al.*, 2012; Lionakis and Levitz, 2018; Saijo *et al.*, 2014; Rosain *et al.*, 2019; Rosen *et al.*, 2013).

Fungal Infections in the Setting of Biological Therapies

In the following sections, the epidemiology and pathogenesis of fungal infections that arise in the setting of mAbs and SMKIs that target various extracellular or intracellular immune molecules will be outlined (Table 1).

Lymphocyte-Depleting Mabs

Alemtuzumab, a humanized mAb that targets cell-surface CD52, causes profound lymphocyte depletion via complement-dependent cytotoxicity and antibody-dependent cell-mediated cytotoxicity (ADCC). While B cell depletion is short-lived, CD4 T cell depletion is prolonged and may last up to 60 months (Cox *et al.*, 2005). Not surprisingly, alemtuzumab-induced lymphocyte depletion predisposes to opportunistic AIDS-defining fungal infections. These include mucosal candidiasis, driven by alemtuzumab-mediated depletion of IL-17-producing Th17 cells and $\gamma\delta$ T cells (Martin *et al.*, 2013), PJP, and, less often, cryptococcosis. Teplizumab, a humanized anti-CD3 mAb, was recently reported to prevent type-1 diabetes in high-risk individuals and

Table 1 Biological therapies associated with fungal infection susceptibility in humans

Biological agent	Drug target	FDA-approved indication(s)	Fungal infection susceptibility	Mechanism(s) of fungal infection susceptibility (when known)
Alemtuzumab	CD52	CLL, MS	Mucosal candidiasis, PJP, cryptococcosis	Profound and prolonged T cell lymphopenia
Rituximab	CD20	CLL, NHL, RA, microscopic polyangiitis, Wegener's granulomatosis	PJP	B cell lymphopenia, impaired T cell responses
Tocilizumab	IL-6R	RA, JIA, giant cell arteritis, cytokine release syndrome (CAR T cell therapy)	Invasive candidiasis, PJP, cryptococcosis, coccidioidomycosis	Impaired phagocyte recruitment and function (<i>Candida</i>)
Secukinumab	IL-17A	Psoriasis, psoriatic arthritis, AS	Mucosal candidiasis	Impaired IL-17 cellular responses
Ixekizumab	IL-17A/IL-17F	N/A		
Bimekizumab	IL-17RA	Psoriasis		
Brodalumab	IL-12p40	Psoriasis, psoriatic arthritis, CD, UC		
Ustekinumab	IL-23p19	Psoriasis CD		
Guselkumab				
Risankizumab				
Tildrakizumab				
Infliximab	TNF- α	Psoriasis, psoriatic arthritis, RA, JIA, AS, CD, UC	IPA, invasive candidiasis, PJP, histoplasmosis, blastomycosis, coccidioidomycosis	Impaired IFN- γ production and granuloma formation (endemic fungi); impaired phagocyte recruitment and activation (<i>Candida</i> and <i>Aspergillus</i>)
Adalimumab				
Etanercept				
Certolizumab pegol				
Golimumab				
Emapalumab	IFN- γ	HLH	PJP, coccidioidomycosis	Impaired IFN- γ cellular responses
Eculizumab	C5a	PNH, HUS	IPA, invasive candidiasis	Impaired phagocyte function
Ibrutinib	BTK	CLL/SLL, MCL, MZL, WM, GvHD	IPA*, mucormycosis, fusariosis, cryptococcosis, PJP, histoplasmosis, blastomycosis	Impaired macrophage activation (<i>Aspergillus</i>); impaired macrophage uptake and IgM production (<i>Cryptococcus</i>)
Acalabrutinib				
Ruxolitinib	JAK1/2/3	Myelofibrosis, polycythemia vera, GvHD, RA, psoriatic arthritis, UC	IPA, PJP, cryptococcosis, talaromycosis, histoplasmosis	Impaired IFN- γ /STAT1 signaling and lymphopenia (endemic fungi); impaired IFN- λ signaling (<i>Aspergillus</i>)
Baricitinib				
Tofacitinib				
Upadacitinib				
Fostamatinib	Syk	ITP	Mucosal candidiasis, skin fungal infection	Impaired IL-17 cellular responses
Sorafenib	B-RAF C-Raf	HCC, RCC	IPA, mucosal candidiasis, <i>Rhodotorula</i> skin infection	Impaired ERK signaling (<i>Aspergillus</i>); impaired T cell responses (<i>Candida</i> , <i>Rhodotorula</i>)
Dasatinib	BCR-ABL	CML	PJP	Impaired T cell activation
Idelalisib	PI3K (p100s)	CLL/SLL, NHL	PJP	Impaired T cell activation
Abatacept	CTLA4	RA, JIA	IPA, invasive candidiasis, PJP, histoplasmosis	Impaired T cell activation (PJP, histoplasmosis)
Natalizumab	α_4 integrin	MS	Cryptococcosis	T cell trafficking

Abbreviations: AS, ankylosing spondylitis; BTK, Bruton's tyrosine kinase; CML, chronic myelogenous leukemia; CTLA4, cytotoxic T-lymphocyte associated protein 4; CAR, chimeric antigen receptor; CD, Crohn's disease; GvHD, graft-versus-host disease; HLH, hemophagocytic lymphohistiocytosis; HUS, hemolytic uremic syndrome; HCC, hepatocellular carcinoma; ITP, idiopathic thrombocytopenic purpura; JIA, juvenile idiopathic arthritis; JAK, Janus kinase; MCL, mantle cell lymphoma; MZL, marginal zone lymphoma; MS, multiple sclerosis; NHL, Non-Hodgkin's lymphoma; N/A, not available. PJP, *Pneumocystis jirovecii* pneumonia; CLL, chronic lymphocytic leukemia; PNH, paroxysmal nocturnal hemoglobinuria; PI3K, phosphoinositide 3-kinase; RAF, rapidly accelerated fibrosarcoma; RCC, renal cell carcinoma; RA, rheumatoid arthritis; SLL, small lymphocytic leukemia; UC, ulcerative colitis; WM, Waldenström macroglobulinemia.

is being evaluated in additional clinical trials of patients with diabetes and psoriasis. Whether teplizumab-treated patients are at risk of developing opportunistic fungal (and non-fungal) infections associated with T cell lymphopenia remains unknown. Importantly, the initial studies in teplizumab-treated patients demonstrated only transient (i.e., <2 weeks) and modest T cell lymphopenia after therapy (Herold *et al.*, 2019), suggestive of a much lower infection risk compared to alemtuzumab.

B cell depletion ensues via complement-dependent cytotoxicity and ADCC with rituximab, a CD20-targeting mouse-human chimeric mAb used to treat a variety of hematological and autoimmune conditions. Although bacterial infections and hepatitis B reactivation are the most common infectious complications following rituximab, several studies have also inferred an increased susceptibility to PJP (Gea-Banacloche, 2010). Besides B cell depletion, mouse studies showed that anti-CD20 treatment-associated

PJP predisposition may relate to impaired anti-*Pneumocystis* CD4 T cell responses (Elsegeiny *et al.*, 2015). Whether the newer-generation B cell-depleting and plasma cell-depleting mAbs also confer PJP susceptibility remains to be determined.

Biologics That Target Cytokine-Mediated Pathways

In recent years, several biologics that target cytokines and/or their receptors have become available for clinical use in a variety of autoimmune and inflammatory conditions (Table 1). Biologic-mediated inhibition of cytokine pathways phenocopies the fungal infection susceptibility (or resistance) profile of the corresponding inherited immune deficiencies of cytokine signaling (Lionakis and Levitz, 2018).

Biologics that target IL-1 receptor (IL-1R) and IL-6 receptor (IL-6R) signaling

Blockade of IL-1 β or its receptor IL-1R by canakinumab or anakinra, respectively, has been successfully used to treat rheumatological disorders without promoting patients' fungal infection susceptibility. Absence of fungal infections in patients treated with IL-1R signaling-targeted biologics is consonant with the lack of fungal infection risk in patients with inborn errors of MyD88 immunity who have defective IL-1R signaling (Picard *et al.*, 2011).

The IL-6R-targeting mAb tocilizumab has proven an effective treatment for rheumatological conditions and for cytokine release syndrome in the setting of chimeric antigen receptor (CAR) T cell therapy. Tocilizumab is well-tolerated from a fungal infection risk standpoint in the vast majority of patients, in agreement with two recent reports of a small number of patients with inherited IL-6R deficiency who developed bacterial, but not fungal, infections (Nahum *et al.*, 2019; Spencer *et al.*, 2019). However, a few sporadic cases of systemic candidiasis, coccidioidomycosis, PJP and cryptococcosis have been reported in tocilizumab-treated individuals, particularly when tocilizumab was combined with other immunomodulatory therapies (Kivitz *et al.*, 2018; Kyriakidis *et al.*, 2017; Nishioka *et al.*, 2018).

mAbs that target IL-17R signaling

Several biologics that inhibit cytokines and/or receptors that are crucial for the effective induction of IL-17R-dependent cellular responses have recently been introduced in the management of psoriasis, psoriatic arthritis, ankylosing spondylitis, and inflammatory bowel diseases (IBD) (Frieder *et al.*, 2018). These biologics inhibit IL-17 cytokines or their receptor directly such as with IL-17A-targeting secukinumab and ixekizumab, IL-17A/IL-17F-targeting bimekizumab, and IL-17RA-targeting brodalumab, or indirectly by inhibiting critical cytokines upstream of IL-17 production such as with IL-12p40-targeting ustekinumab, and IL-23p19-targeting guselkumab, risankizumab, and tildrakizumab. As observed with patients suffering from inborn errors of IL-17R-dependent signaling (Puel *et al.*, 2011, 2012), patients treated with IL-17-targeted biologics are also at risk for refractory mucocutaneous candidiasis, but not systemic candidiasis or other IFIs, further attesting to the fundamental role of IL-17R signaling in antifungal mucosal immunity in humans. However, despite the ~80%–90% inhibition of IL-17R cellular responses that is achieved at the mucocutaneous barrier by the aforementioned IL-17R-targeted biologics (Krueger *et al.*, 2012, 2019; Tomalin *et al.*, 2019), only a small proportion of treated patients (i.e., 2%–5%) develop mucosal fungal disease, with a greater infection frequency observed in patients receiving IL-17RA- and IL-23p19-targeted molecules relative to those receiving IL-17A-, IL-17A/IL-17F-, and IL-12p40-targeted molecules (Saunte *et al.*, 2017). These observations indicate that humans can tolerate a ~80%–90% inhibition of IL-17-dependent cellular responses without significant mucosal fungal infection consequences, and that a deeper, >90%–95% inhibition is required to induce mucosal fungal disease, as seen with the inherited, complete, IL-17R/ACT1 deficiencies.

TNF- α -targeting biologics

Infliximab, a humanized mAb against TNF- α , was the first biologic that was linked to susceptibility to opportunistic infection in 2001, namely tuberculosis, including severe extrapulmonary and/or disseminated disease (Keane *et al.*, 2001). Beyond tuberculous and non-tuberculous mycobacterial disease, TNF- α blockade, which is now widely used for the treatment of IBD and rheumatoid arthritis (RA), also predisposes to infections by other intra-macrophage pathogens such as PJP and the endemic dimorphic fungi *Histoplasma*, *Blastomyces*, and *Coccidioides*. Mechanistically, TNF- α inhibition abrogates IFN- γ production and IFN- γ -mediated macrophage activation, and impairs granuloma formation, which are all detrimental for intracellular pathogen control. The risk of opportunistic fungal (and mycobacterial) infection upon TNF- α blockade is greater with the anti-TNF- α mAbs infliximab and adalimumab as compared to the soluble TNF- α receptor etanercept. This differential infection risk is accounted for by fact that the anti-TNF- α mAbs mediate complement-induced lysis of TNF- α -expressing cells and inhibit both cell-associated and soluble TNF- α , as opposed to etanercept that only inhibits soluble TNF- α . In addition, TNF- α inhibitors have been associated with the development of invasive candidiasis and IPA; mechanistically, impaired phagocyte recruitment and activation in the setting of TNF- α blockage may underlie such susceptibility (Lionakis and Levitz, 2018).

IFN- γ -targeting mAb

Emapalumab is a humanized mAb against IFN- γ , which received FDA approval in 2018 for the treatment of pediatric and adult patients with refractory primary hemophagocytic lymphohistiocytosis (HLH), an IFN- γ -driven immune dysregulation condition (Burn *et al.*, 2019; Lounder *et al.*, 2019; Vallurupalli and Berliner, 2019). In addition, emapalumab is currently being evaluated for

the management of secondary HLH in the setting of systemic juvenile idiopathic arthritis. Given the central role of IFN- γ in orchestrating effective host defense against intracellular pathogens including viruses, mycobacteria and fungi (Lionakis and Levitz, 2018), emapalumab-treated patients are at risk for such infections. Indeed, fungal infections including cases of disseminated coccidioidomycosis and PJP have been reported in 9% of emapalumab-treated patients based on the drug's FDA package insert.

GM-CSF receptor (GM-CSFR)-targeting mAb

Mavrilimumab is a humanized monoclonal antibody that targets GM-CSFR. The drug has exhibited clinical efficacy in patients with rheumatoid arthritis in early clinical trials and is currently also being evaluated for the treatment of giant cell arteritis. No significant infection risk has been revealed in the relatively small number of patients that have been enrolled in the early clinical trials thus far, except for a small percent of patients who were reported to develop pneumonia, for which no information about the pathogen was provided (Burmester *et al.*, 2017, 2018; Takeuchi *et al.*, 2015; Weinblatt *et al.*, 2018). Given the importance of GM-CSF in host defense against cryptococcosis in humans (Rosen *et al.*, 2013; Saijo *et al.*, 2014) and the indispensable role of GM-CSF in anti-*Aspergillus* innate immunity in mice (Kasahara *et al.*, 2016), surveillance will be required in mavrilimumab-treated individuals to determine their potential risk of developing such opportunistic fungal infections.

Complement-Targeting Biologics

Terminal complement factor deficiency in the form of inherited C5a deficiency is known to predispose to severe infections by encapsulated bacteria including pneumococcus, *Haemophilus* and *Neisseria*; mucosal candidiasis has also rarely been reported in these patients (Rosenfeld *et al.*, 1976). Eculizumab is a humanized C5-targeting mAb that causes iatrogenic terminal complement deficiency, it has been successfully used to treat patients with a variety of hemolytic disorders, and it carries a significant risk for infection by encapsulated bacteria. In 2018, the FDA updated eculizumab's package insert to also alert for the potential risk of IFIs, including IPA, especially in patients with low neutrophil counts and/or those receiving other immunomodulatory medications. Post-marketing surveillance studies have indeed uncovered cases of IPA and invasive candidiasis in eculizumab-treated patients (Socie *et al.*, 2019). Moreover, in a small study of eculizumab-treated allogeneic HSCT recipients with transplant-associated thrombotic microangiopathy (TA-TMA), a striking 20% incidence of IMIs despite receipt of mold-active antifungal prophylaxis was reported as opposed to no IMIs developing in HSCT recipients with TA-TMA who did not receive eculizumab (Bohl *et al.*, 2017). Mechanistically, C5 genetic deficiency in mice results in significantly greater mortality following systemic infection with *Candida* and *Aspergillus* and C5 is important for the antifungal effector function of mouse and human myeloid phagocytes (Ashman *et al.*, 1993; Hunniger *et al.*, 2015). Therefore, more clinical studies are needed to precisely define the relative contribution of eculizumab, used alone or in combination with other immune modulators, in promoting opportunistic fungal disease. Notably, the advent of additional biologics that target the complement axis in loci that have been shown to be crucial for antifungal surveillance in mice such as the C3 inhibitor APL-2 and the C5AR1 antagonist avacopan, which recently showed clinical efficacy in steroid-refractory ANCA-positive vasculitis (Jayne *et al.*, 2017; Tsoni *et al.*, 2009; Zipfel *et al.*, 2019), will require clinical surveillance to determine whether they may confer fungal infection susceptibility.

mAbs That Target Checkpoint Pathways

The development of mAbs that block the checkpoint molecules programmed cell death protein 1 (PD-1) and cytotoxic T-lymphocyte associated protein 4 (CTLA-4) has revolutionized the treatment of a wide array of malignancies. These checkpoint inhibitors (CPIs) do not predispose to fungal disease; instead CPIs show promise as potential adjunct immunotherapy for certain fungal infections. However, immune-related adverse events (irAEs) occur often following CPI treatment and are major causes of morbidity and, in some instances, mortality. The management of irAEs requires immunomodulatory intervention with TNF- α inhibitors and/or corticosteroids, which themselves predispose to opportunistic fungal (and other) infections [reviewed in detail elsewhere (Abers *et al.*, 2019)].

SMKI

SMKIs that inhibit various intracellular molecules have emerged as effective therapeutic modalities for several neoplastic and inflammatory diseases (Table 1). The inhibition of certain signaling pathways by such SMKIs has resulted in either expected or unexpected fungal infection susceptibility profiles in treated patients, while other SMKIs that are currently being evaluated in early clinical trials are predicted to enhance fungal infection risk based on the indispensable role of the corresponding pathway that they inhibit in antifungal host defense. In this section, the epidemiology and pathogenesis of fungal infections that have developed or are expected to develop in the setting of key SMKIs is discussed.

SMKIs targeting BTK signaling

Ibrutinib is an irreversible inhibitor of the Bruton's tyrosine kinase (BTK) that blocks B cell receptor signaling activation and impairs B cell development and survival in hematologic malignancies. Indeed, ibrutinib has become a game-changing therapeutic modality in chronic lymphocytic leukemia (CLL), and has also shown clinical efficacy against other B cell-targeted hematologic

malignancies such as diffuse large B cell lymphoma, mantle cell lymphoma, marginal zone lymphoma, Waldenström macroglobulinemia, and primary CNS lymphoma (PCNSL), as well as graft-versus-host disease (GvHD) following HSCT (Chamilos *et al.*, 2018; Zarakas *et al.*, 2019).

The development of IFIs during ibrutinib-based therapy has been a somewhat surprising clinical observation, because (a) patients with X-linked agammaglobulinemia caused by germline *BTK* mutations seldom develop fungal disease (Kanegane *et al.*, 2009; Nishi *et al.*, 2018), and (b) B cells, the primary cellular target of ibrutinib-induced BTK inhibition, are considered less critical for fungal host defense relative to T cells and myeloid phagocytes (Lionakis and Levitz, 2018). Taken together, the clinical experience indicates that ibrutinib-associated IFIs most often consist of IMIs (IPA much more often than mucormycosis and fusariosis), followed by cryptococcosis, followed by PJP, followed by endemic fungal disease (i.e., histoplasmosis, blastomycosis). In patients traditionally considered low-risk for development of IFIs such as those with CLL or non-Hodgkin's lymphoma (NHL) (incidence, <1%) (Pagano *et al.*, 2006), the incidence of IFIs associated with ibrutinib monotherapy is estimated at 2.4%–4.2% (Rogers *et al.*, 2019; Ruchlemer *et al.*, 2019; Varughese *et al.*, 2018). When ibrutinib is used in combination with corticosteroids, the incidence of IFIs is estimated at 5%–11% (Grommes *et al.*, 2017; Lakshmanan and Byrd, 2017). When ibrutinib is used in combination with corticosteroids and chemotherapeutic or other biological therapies, the incidence of IFIs can be as high as 39%, as shown in PCNSL patients (Lionakis *et al.*, 2017a).

A few clinical observations that relate to ibrutinib-associated IFIs are worthwhile briefly highlighting. Firstly, the majority of such IFIs develop within the first 2–3 months after initiation of ibrutinib and often occur in the absence of traditional risk factors for IFIs such as neutropenia (for IMIs) or lymphopenia (for cryptococcosis or PJP) (Ghez *et al.*, 2018; Ruchlemer *et al.*, 2019; Varughese *et al.*, 2018). Secondly, ibrutinib-associated IFIs feature rapid clinical progression unless ibrutinib is promptly discontinued, and they carry a remarkably high frequency of dissemination including CNS involvement (up to ~45%) and high mortality (30%–70%) (Lionakis *et al.*, 2017a; Ghez *et al.*, 2018).

Mechanistically, BTK is thought to protect from IPA via its expression on macrophages, whereas it acts downstream of TLR9- and Dectin-1-mediated *Aspergillus* recognition to promote NFAT/NFκB-dependent TNF-α secretion upon *Aspergillus* stimulation (Bercusson *et al.*, 2018; Herbst *et al.*, 2015). In agreement, Btk-deficient mice and myeloid phagocyte-specific conditional Btk-knockout mice are susceptible to IPA and exhibit defects in phagocyte anti-*Aspergillus* effector function (Lionakis *et al.*, 2017a), (Lionakis lab, unpublished). In addition, BTK is thought to protect from cryptococcosis via promoting phagocytosis of *Cryptococcus* yeasts by alveolar macrophages and generation of protective anti-*Cryptococcus* IgM (Szymczak *et al.*, 2013). The mechanisms by which BTK orchestrates macrophage-T cell cross-talk to protect against PJP remain unknown thus far.

SMKIs targeting JAK-STAT signaling

The JAK inhibitors ruxolitinib, baricitinib, tofacitinib and upadacitinib inhibit JAK/STAT signaling and, as a result, inhibit the activation of mononuclear phagocytes and down-regulate the production of a wide array of inflammatory mediators including common γ-chain cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21), type-I interferons (IFN-α, IFN-β), type-II interferon (IFN-γ), type-III interferons (e.g., IFN-λ), as well as IL-6, IL-10, IL-12, IL-22, IL-23 and GM-CSF [reviewed in detail elsewhere (Bechman *et al.*, 2019b; O'Shea *et al.*, 2013; Moodley *et al.*, 2016)].

JAK/STAT inhibitors are now widely used in the treatment of a broad spectrum of inflammatory and neoplastic conditions including myelofibrosis, polycythemia vera, steroid-refractory GvHD, rheumatoid arthritis, psoriatic arthritis, and ulcerative colitis, and opportunistic viral, mycobacterial and fungal disease has been reported in some patients (Bechman *et al.*, 2019a). Given the critical contribution of the lymphocyte-macrophage cross-talk in host defense against intracellular pathogens, JAK/STAT inhibitors have been associated with development of cryptococcosis, histoplasmosis, talaromycosis and PJP, via inducing lymphopenia and abrogating IFN-γ/STAT1 signaling within macrophages (Chan *et al.*, 2015; Dioverti *et al.*, 2018; Prakash and Richman, 2019). In addition, the recent recognition that IFN-λ/IFNLR1 signaling is critical for neutrophil oxidative burst and *Aspergillus* killing in mice indicates that aspergillosis and other IMIs may occur in the setting of JAK/STAT inhibition in humans (Espinosa *et al.*, 2014); indeed, a few such IPA cases are now emerging in the literature (Moruno-Rodriguez *et al.*, 2019; Polverelli *et al.*, 2017).

SMKIs targeting CLR-Spleen tyrosine kinase (Syk)-CARD9 signaling

Fostamatinib is a Syk inhibitor that was recently FDA-approved for the treatment of immune thrombocytopenic purpura, and is currently being evaluated in a variety of other inflammatory and neoplastic conditions including acute myelogenous leukemia, NHL, GvHD, renal transplant rejection, systemic lupus erythematosus, RA, autoimmune hemolytic anemia, and IgA nephropathy (See "Relevant Website section").

Syk is an important intracellular kinase that relays fungal-sensing signals downstream of the CLR family of pattern recognition receptors through the adaptor CARD9 for induction of protective innate and adaptive immune responses (Gross *et al.*, 2006; Drummond *et al.*, 2018). Given the profound fungal-specific infection susceptibility of patients with inherited CARD9 deficiency, it is expected that iatrogenic, fostamatinib-induced Syk/CARD9 signaling inhibition will heighten the risk of opportunistic fungal disease in fostamatinib-treated patients. The infection susceptibility phenotype of CARD9-deficient maps to 4 fungal diseases: (a) mucosal candidiasis, associated with IL-17R signaling defects (Glocker *et al.*, 2009; Lanternier *et al.*, 2015b; LeibundGut-Landmann *et al.*, 2007), (b) CNS candidiasis, associated with impaired neutrophil *Candida* killing and impaired microglial responses that lead to defective neutrophil recruitment to the fungal-infected CNS (Drewniak *et al.*, 2013; Drummond *et al.*, 2015, 2019), (c) extrapulmonary aspergillosis, associated with impaired neutrophil recruitment to infected tissues while neutrophil *Aspergillus* killing remains intact (De Bruyne *et al.*, 2018; Rieber *et al.*, 2016), (d) severe subcutaneous dermatophytosis and phaeohyphomycosis (some of which disseminate in deep tissues including the CNS), typically

following traumatic fungal inoculation, via mechanisms that remain to be elucidated (Lanternier *et al.*, 2015a, 2013). Therefore, surveillance of fostamatinib-treated patients for the development of the aforementioned fungal diseases is warranted. In fact, a case of vaginal yeast infection has been described in a fostamatinib-treated woman with hematological malignancy (Friedberg *et al.*, 2010) and a case of skin fungal infection has been described in one of the 18 fostamatinib-treated patients with T-cell lymphoma (incidence 5.6%) (clinicaltrials.gov, NCT00798096).

SMKIs targeting MAPK and other intracellular pathways

The emergence of several other SMKIs that target key intracellular pathways of antifungal host surveillance has been accompanied by development of opportunistic fungal disease. Some such examples are worthwhile briefly mentioning. For example, sorafenib inhibits multiple cell-surface and intracellular kinases within the RAS/MAPK signaling cascade and blocks the function of BRAF, Raf-1, RAS/ERK (extracellular signal-regulated kinase), and MEK (mitogen-activated kinase/ERK) pathway (Wilhelm *et al.*, 2004). Sorafenib-treated patients have been reported to develop IPA in the absence of other iatrogenic risk factors (Bazaz and Denning, 2018) and mucocutaneous fungal infections by *Rhodotorula* and *Candida* (Chen *et al.*, 2016; Coppola *et al.*, 2015). Mechanistically, sorafenib-induced inhibition of ERK signaling, which is critical for phagocyte *Aspergillus* killing, may underlie susceptibility to IPA (Dubourdeau *et al.*, 2006), while sorafenib-induced inhibition of NF- κ B and PI3 (phosphoinositide 3-kinase), which is important for impaired T cell responses via affecting dendritic cell-dependent antigen presentation (Hipp *et al.*, 2008), may underlie mucosal fungal infection susceptibility.

Furthermore, the BCR/ABL tyrosine kinase dasatinib and the PI3K inhibitor idelalisib have been associated with susceptibility to PJP (Chang *et al.*, 2014; Hipp *et al.*, 2008), the CTLA4 modulator abatacept has been associated with development of PJP, IPA, histoplasmosis and invasive candidiasis (Buch *et al.*, 2008; Jain *et al.*, 2018; Kyriakidis *et al.*, 2017), and natalizumab that targets α_4 integrin and inhibits lymphocyte trafficking to the CNS in multiple sclerosis patients has been associated with development of cryptococcosis (Valenzuela *et al.*, 2014).

Conclusion

The recent explosion in the use of mAbs and SMKIs for the treatment of malignant and autoimmune conditions has been associated with the development of mucosal and/or life-threatening IFIs driven by complex iatrogenic immunodeficiency states in treated patients and has uncovered the critical contribution of certain immune-related molecules and pathways in human antifungal host defense. Moving forward, increased awareness among clinicians, improved surveillance and reporting of opportunistic infections during clinical trials, and research to better understand the epidemiology of fungal infections associated with biological therapies and the effects of these molecules on immune responses should help devise better strategies for the diagnosis, prophylaxis and treatment of such opportunistic infections and improve patient outcomes.

Uncommon Yeast-Like Pathogens

Malassezia Species

Introduction

Members of the *Malassezia* genus are lipophilic, basidiomycetous yeasts belonging to the subphylum Ustilaginomycotina and the class Malasseziomycetes. There are currently 18 recognized species: *M. furfur*, *M. globosa*, *M. restricta*, *M. obtusa*, *M. sympodialis*, *M. pachydermatis*, *M. japonica*, *M. yamatoensis*, *M. dermatis*, *M. nana*, *M. caprae*, *M. equina*, *M. slooffiae*, *M. cuniculi*, *M. brasiliensis*, *M. psittaci*, *M. arunalokei*, and *M. verspertilionis* (Lorch *et al.*, 2018; Wang *et al.*, 2014). Unique among *Malassezia* species, *M. pachydermatis* is the only species not dependent on lipids for growth. *Malassezia* species are predominantly plant and animal pathogens, but do comprise an estimated 50%–80% of the human skin mycobiome, with *M. globosa*, *M. restricta*, and *M. sympodialis* most frequently isolated (Findley *et al.*, 2013). Recently, *Malassezia* species within the gut microbiome have been linked to the progression of pancreatic cancer through interaction with the complement cascade (Aykut *et al.*, 2019).

Clinical presentation

Malassezia species are associated with several cutaneous diseases, namely seborrheic dermatitis, pityriasis (tinea) versicolor, folliculitis, atopic dermatitis and, occasionally, onychomycosis. Systemic infections most frequently occur in premature neonates receiving lipid-rich total parenteral nutrition, immunocompromised children, and adults with indwelling central venous catheters (Arendrup *et al.*, 2009; Shparago *et al.*, 1995). Additional risk factors for invasive disease include hematologic malignancy and peritoneal dialysis. Almost all reported systemic human infections are caused by *M. furfur* and *M. pachydermatis*, with the latter considered zoonotic, passing to immunosuppressed patients from pets. While fungemia is the most commonly reported site of invasive infection, *Malassezia* has also been implicated in catheter-associated peritonitis (Johnson *et al.*, 1996), meningitis (Rosales *et al.*, 2004), and sinopulmonary infection (Redline and Dahms, 1981). Furthermore, nosocomial outbreaks of *Malassezia* fungemia and folliculitis have been reported in intensive care units, with the hypothesized transmission of *M. pachydermatis* from the hands of healthcare workers that owned pet dogs (Archer-Dubon *et al.*, 1999; Chang *et al.*, 1998).

Diagnosis and identification

The diagnosis of invasive *Malassezia* infection is made by isolation in laboratory culture from a sterile site. This is often challenging, as most culture media are not enriched with lipid nutrients required to support *Malassezia* growth. Thus, any clinical specimen with positive staining for yeast forms and negative culture growth should prompt consideration of *Malassezia*. Use of modified Dixon agar, Leeming-Notman agar, CHROMagar, and Sabouraud's agar with sterile olive oil will allow for recovery of *Malassezia* from clinical samples (Iatta *et al.*, 2018). *Malassezia pachydermatis* is the exception, and does not require lipid supplementation for growth.

Once present in culture, *Malassezia* colonies grow rapidly over 5 days at 30–37°C. Colonies appear creamy yellow to brown, initially smooth and raised, and wrinkle over time. Microscopically, *Malassezia* species form small, elongated blastoconidia which demonstrate unipolar budding (Kaneko *et al.*, 2007) and yeast cells may have the appearance of a wine flask structure.

Distinction between species is achieved by a variety of methods. Previously, species identification was made by a combination of morphology and biochemical testing, including Tween test, esculine splitting test, and catalase and urease reactions (Kaneko *et al.*, 2007; Marcon and Powell, 1987). However, these methods are complex, laborious, and occasionally inaccurate. As a result, they have been replaced largely by PCR based methods. Species-level identification can be made through sequence analysis of the internal transcribed spacers (ITS) and D1/D2 domains of the large ribosomal subunit (Ilahi *et al.*, 2017; Makimura *et al.*, 2000). More recently, several studies have shown that matrix-associated laser desorption/ionization-time of flight (MALDI-TOF) is a promising modality for identification of *Malassezia* at the species level (Denis *et al.*, 2017; Honnavar *et al.*, 2018; Kolečka *et al.*, 2014).

Treatment and outcomes

Susceptibility testing is primarily reserved for strains causing invasive infection, and therefore, mostly restricted to *Malassezia furfur* and *Malassezia pachydermatis*. However, there are no standardized clinical breakpoints for *Malassezia* species. Various methods have been used for susceptibility testing, including modified microdilution and E-test (Cafarchia *et al.*, 2012; Velegriaki *et al.*, 2004). Modified disk diffusion testing has shown poorer correlation with microdilution testing, and its clinical application remains uncertain (Rojas *et al.*, 2017). Minimum inhibitory concentrations for itraconazole and posaconazole are lower than those for fluconazole and voriconazole (Cafarchia *et al.*, 2015; Cafarchia *et al.*, 2012; Iatta *et al.*, 2014; Schmidt and Ruhl-Horster, 1996). Susceptibility testing for amphotericin B demonstrates lower MIC values for the liposomal formulation, which is likely due to the lipophilic nature of these fungi (Alvarez-Perez *et al.*, 2014; Iatta *et al.*, 2015). *Malassezia* species are uniformly resistant to echinocandins and flucytosine, and these antifungal agents should not be used to treat invasive disease. Currently, no rigorous clinical

studies exist to inform optimal medical therapy. Liposomal amphotericin B is the agent of choice, which is occasionally combined with a second agent, usually an azole. Treatment duration is not standardized and has ranged from anywhere from three days to fifty days in the medical literature (Pedrosa *et al.*, 2018). Removal of indwelling central venous catheters and discontinuation of lipid-rich total parenteral nutrition are critical for rapid treatment of *Malassezia*. This is so important that the exact antifungal agent used has less impact on outcome for these fungi which are not facile at producing clinical disease.

Pseudozyma Species

Introduction

Pseudozyma species (recently renamed as *Moesziomyces*) are basidiomycetous, true smut fungi belonging to the Ustilaginales order. Predominantly plant pathogens, the first cases of invasive human disease were reported in 2003 (Sugita *et al.*, 2003). There are currently over twenty species within the genus. Members implicated in human disease include *P. aphidis*, *P. antarctica*, *P. parantarctica*, *P. thailandica*, *P. alboarmeniaca*, *P. crassa*, and *P. siamensis* (Mekha *et al.*, 2014; Sugita *et al.*, 2003). *P. aphidis* is responsible for the vast majority of reported infections.

Clinical presentation

The majority of human disease is caused by either *P. aphidis* or undifferentiated *Pseudozyma* species. Infections have been reported in patients with hematologic malignancy, neutropenia, advanced age or prematurity, underlying gastrointestinal illness, or indwelling central venous catheters (Pande *et al.*, 2017; Prakash *et al.*, 2014). Of the eleven published cases, fungemia is most commonly observed. However, brain abscess, post-surgical endophthalmitis, mycetoma, and pneumonia have also been reported (Hwang *et al.*, 2010; Joo *et al.*, 2016; Parahym *et al.*, 2013; Voon *et al.*, 2019). Clinical signs and symptoms are protean, and depend upon location of infection.

Diagnosis and identification

Diagnosis is made by culture of *Pseudozyma* from a sterile site. These fungi will grow readily on Sabouraud dextrose agar at 30–37°C. When isolated, rapidly expanding, orange-white, wrinkled colonies develop. Microscopically, *Pseudozyma* demonstrate fusiform yeasts budding from short stalks, and form elongated, ellipsoidal blastoconidia on slide culture (Sugita *et al.*, 2003).

Species identifications through morphological and biochemical testing are difficult, time-intensive and unreliable. *P. aphidis*, the primary isolated pathogen, assimilates D-galactose, lactose, and melibiose but not ethanol, which may help distinguish it from other members of the *Pseudozyma* genus (Hwang *et al.*, 2010). However, identification is most often made by molecular probing of the ITS DNA between ribosomal domains and D1/D2 domain of the 26S ribosomal subunit (Siddiqui *et al.*, 2014). Unfortunately, MALDI-TOF at present cannot reliably distinguish *Pseudozyma* at the genus or species level.

Therapy and outcomes

Given the rarity of infection, no standardized susceptibility testing for *Pseudozyma* species currently exists. Low MICs to amphotericin B, voriconazole, posaconazole, and isavuconazole have been reported, but most clinically isolated specimens have high MICs to fluconazole (Joo *et al.*, 2016). Echinocandin and flucytosine resistance is intrinsic. Amphotericin B or voriconazole are recommended as first-line therapy, and suggested by the European Society of Clinical Microbiology and Infectious Diseases and European Confederation of Medical Mycology guidelines (Arendrup *et al.*, 2014). Most reported cases have been treated with a two-week course of therapy and central venous catheter removal (Pande *et al.*, 2017). Of the eleven cases reported in literature, outcomes have been generally good, with only one fatality reported in a patient with a *Pseudozyma* brain abscess (Hwang *et al.*, 2010).

Rhodotorula Species

Introduction

Originally believed to be a non-pathogenic red yeast, the first case of *Rhodotorula* infection in humans was reported in 1960 (Louria *et al.*, 1960). Since then, well over 240 cases have been reported in the medical literature. Fungi belonging to the *Rhodotorula* genus are imperfect basidiomycetes within the Sporidiobolaceae family (Urbina and Aime, 2018). They are widely disseminated in nature and have been cultured from air, soil, saltwater, plants and household fixtures (Galan-Sanchez *et al.*, 1999). *Rhodotorula* species have been isolated from the skin, respiratory, alimentary, and urinary tracts of humans and form a small, but important, part of the human mycobiome (Monteiro-da-Silva *et al.*, 2014). While there are many *Rhodotorula* species, only three are reported to cause disease in humans. These are *R. mucilaginosa* (formerly *R. rubra*), *R. glutinis*, and *R. minuta*. Of these, *R. mucilaginosa* accounts for the vast majority of human infections.

Clinical presentation

Fungemia is the most frequent syndrome witnessed in humans, representing approximately 60% of all infections caused by *Rhodotorula* species, which comprise 0.5%–2.3% of bloodstream infections caused by all fungal pathogens (Ioannou *et al.*, 2019). Most disease occurs in patients with indwelling central venous catheters with underlying hematologic or solid organ malignancies (Garcia-Suarez *et al.*, 2011). Other risk factors include chronic kidney disease, continuous ambulatory peritoneal dialysis, cirrhosis,

total parenteral nutrition, and solid organ or stem cell transplantation (Lunardi *et al.*, 2006; Wirth and Goldani, 2012). Of note, breakthrough cases of fungemia have been described in patients on fluconazole and posaconazole prophylaxis. Endocarditis, while extremely rare, complicates around 5% of all *Rhodotorula* fungemia, and should be considered as a potential diagnosis in fungemic patients (Simon *et al.*, 2014).

It is clear that *Rhodotorula* displays neurotropism, with a propensity to cause meningitis, often in patients with AIDS or underlying autoimmunity (Menon *et al.*, 2014; Mohd Nor *et al.*, 2015). However, cases have been reported in patients without known immunocompromise. Symptoms of meningitis may be acute, subacute, or chronic. Importantly, *Rhodotorula* meningitis may be mistaken for cryptococcal meningitis, which is a much more commonly encountered central nervous system infection. Appropriate identification is imperative to ensure correct clinical management as treatment of *Cryptococcus* and *Rhodotorula* differs.

Ocular infections and catheter-associated peritonitis make up most of the remaining reported cases of *Rhodotorula* infection. Keratitis and scleritis are often preceded by orbital surgery or trauma, while endophthalmitis occurs endogenously in patients with AIDS or intravenous drug use (Luong *et al.*, 2017; Merkur and Hodge, 2002). Other less frequently observed infections include skin infections, joint infections, intraabdominal and urinary tract infections (Diktas *et al.*, 2013; Savini *et al.*, 2008; Seyfarth *et al.*, 2012).

Diagnosis and identification

As part of the human mycobiome, *Rhodotorula* is a common cause of either laboratory contamination or colonization. Therefore, patients with positive cultures for *Rhodotorula* should have accompanying signs and symptoms consistent with infection for diagnosis (i.e., fever, tachycardia, hypotension, leukocytosis, etc.). When isolated, these fungi are non-fastidious and grow rapidly on most media. On Sabouraud agar they form characteristic coral red colonies, although orange and pink colonies may also be seen. Microscopically, they appear as round or ovoid budding yeasts without formation of pseudohyphae. They may be mistaken for *Cryptococcus* species, but can be easily distinguished by their inability to assimilate inositol. *R. mucilaginosa* can be differentiated from *R. glutinis* by its inability to assimilate nitrate. While the pathogenic species of *Rhodotorula* can be discriminated by morphology and biochemical testing, PCR and mass spectrometry (MALDI-TOF) techniques also provide reliable identification at a species level (Lohmann *et al.*, 2013; Saracli *et al.*, 2003b).

Therapy and outcomes

Treatment of *Rhodotorula* infections is managed with prompt initiation of antifungal agents, removal of indwelling catheters, and restoration of host immunity. As with other rare fungal pathogens, there are no standardized *in vitro* antifungal drug susceptibility breakpoints, but multiple studies have demonstrated both amphotericin B and flucytosine possess excellent *in vitro* activity (Falces-Romero *et al.*, 2018; Nunes *et al.*, 2013). Importantly, *Rhodotorula* species are intrinsically resistant to fluconazole. Reported MICs are consistently greater than 32 µg/ml, and thus, fluconazole cannot be recommended for therapy. As *Rhodotorula* species are most often mistaken with *Cryptococcus* species, which are fluconazole susceptible, proper identification is imperative. Itraconazole, voriconazole and posaconazole all appear to have some activity against *Rhodotorula*, while studies suggest isavuconazole may be an alternative to first-line therapy (Gomez-Lopez *et al.*, 2005). Echinocandins should not be used for treatment of *Rhodotorula* infections. Research into combination therapy in the treatment of *Rhodotorula* is sparse and cannot form the basis for any specific clinical recommendations at this time.

Clinical outcomes range widely depending upon the nature of the underlying infection. Mortality attributable to infection in patients with fungemia approximates 10%, while the attributable mortality in *Rhodotorula* meningitis is around 40% (Ioannou *et al.*, 2019). Ocular infections have not been associated with mortality, but often result in significant morbidity with visual loss and enucleation reported. Duration of therapy varies widely in published case reports.

Saccharomyces Cerevisiae (Var Boulardii)

Introduction

Saccharomyces cerevisiae and its variant *Saccharomyces boulardii*, otherwise known as “baker’s yeast” (or “brewer’s yeast”), are ubiquitous in nature, cultivated from soil, plants, and fruit, and are occasionally isolated from the human genitourinary and gastrointestinal tracts (Hallen-Adams and Suhr, 2017; Rose and Kurup, 1977). It is a major model yeast for study of molecular biology, genetics, and biochemistry. Taxonomically, they are ascomycetous fungi belonging to the class Hemiascomycetes, order Saccharomycetales, and family Saccharomycetaceae. Previously thought to be a separate species, *Saccharomyces boulardii* is now considered a variant of *Saccharomyces cerevisiae* on the basis of molecular testing (McCullough *et al.*, 1998). *Saccharomyces* is frequently utilized in the preparation of probiotics to treat and prevent a variety of gastrointestinal illnesses, including *Clostridioides difficile* infection. The first case of invasive *Saccharomyces* disease was reported in 1970 in a woman with prosthetic valve endocarditis (Stein *et al.*, 1970). Since that time, it has been implicated in various clinical syndromes.

Clinical presentation

Saccharomyces has been implicated in a number of infections in humans including empyema, liver abscess, esophagitis, peritonitis and urinary tract infection (Aucott *et al.*, 1990; Chertow *et al.*, 1991; Snyder, 1992). However, the most commonly encountered syndrome is fungemia (Enache-Angoulvant and Hennequin, 2005). Infection occurs in both immunocompromised and immunocompetent individuals, with the former group at higher risk of dissemination. Premature neonates, persons receiving parenteral

nutrition, critically-ill patients and those with intravenous catheters appear to be at highest risk. Exposure to *Saccharomyces*-containing probiotics constitutes a primary risk factor for disease, and nosocomial transmission of infection from healthcare workers has also been reported (Cassone *et al.*, 2003; Lherm *et al.*, 2002). It is recommended that probiotics containing *Saccharomyces* not be used in seriously ill, immunocompromised patients. Infection is theorized to occur by either translocation across disrupted mucosal barriers, or through decreased skin integrity (i.e., venous catheters). These species are capable of forming biofilms to allow persistence on catheters (Helmuth, 2001). In a small proportion of women, *Saccharomyces* can also cause recurrent, difficult-to-treat azole-resistant vulvovaginitis (Sobel *et al.*, 1993). Vaginitis caused by *Saccharomyces* species is clinically indistinguishable from that caused by more common *Candida* species.

Diagnosis and identification

Diagnosis of infection is made by isolating this yeast from a sterile body site. As *Saccharomyces* are only intermittent colonizers of humans, positive cultures from the bloodstream should lead to strong consideration of invasive disease. Identification is readily made by morphological evaluation and biochemical testing. On Sabouraud agar, smooth, moist, cream-colored colonies grow rapidly in 3 days. On CHROMagar these colonies appear dark pink. They are able to ferment carbohydrates and assimilate raffinose, but cannot assimilate nitrate. Microscopically, yeast cells are round or ovoid, measure 5–10 μ , and are slightly larger than *Candida glabrata*. *Saccharomyces* species do not form hyphae, but may form pseudohyphae when starved for nitrogen. On nutrient-depleted media, *S. cerevisiae* can sporulate to form one to four ascospores per ascus. β -1,3-D-glucan has been detected both *in vitro* and *in vivo* from clinical specimens, however the clinical utility of serologic testing has not been evaluated (Odabasi *et al.*, 2006; Yoshida *et al.*, 1997).

Molecular methods allow for identification at the species level through PCR based techniques targeting the ITS2 region or the 26S rRNA gene. MALDI-TOF-MS has also demonstrated capability to discriminate *Saccharomyces* at the species level (Marklein *et al.*, 2009).

Therapy and outcomes

MIC testing against *Saccharomyces* isolates may be performed by micro- or macro-dilution and disk diffusion methods. While no standardized breakpoints exist, CLSI guidelines for *Candida* species were previously used for interpretation. After breakpoints for *Candida* were made species-specific in 2012, *Saccharomyces* isolates appear to closely mirror *in vitro* *C. glabrata* susceptibilities. Amphotericin B, flucytosine, and echinocandins seem to have reliable *in vitro* efficacy against *Saccharomyces* species, while MICs for fluconazole show wide variability. Extended spectrum azoles likely have excellent *in vitro* activity (Thompson *et al.*, 2009). Amphotericin B or fluconazole are most commonly used clinically with reasonable clinical success—occasionally in contrast to the *in vitro* data – which speaks to the low pathogenicity and virulence of *Saccharomyces*. Clinical experience with echinocandin therapy is scarce, but has been effective in at least two cases (Lolis *et al.*, 2008; Roy *et al.*, 2017) and probably is a first-line treatment agent. Combination therapy has been previously described for recurrent disease, but its role remains inconclusive (Davies *et al.*, 2019). As with most invasive fungal infections, removal of central venous catheters is an important aspect of therapy, due to the ability of *Saccharomyces* to form well-developed biofilms. All-cause mortality rates for invasive *Saccharomyces* infection are estimated around 25%, but this is thought to reflect underlying host morbidity rather than pathogenicity of *Saccharomyces*.

Saprochaete Species

Introduction

Saprochaete capitata (formerly *Geotrichum capitatum* or *Blastoschizomyces capitatus*) and *Saprochaete clavata* (previously *Geotrichum clavatum*) are non-fermentative, urease-negative, ascomycetous yeasts. The teleomorphic form of *S. capitata* is identified as *Magnusiomyces capitatus*. Currently, they are classified in the subphylum Saccharomycotina, class Saccharomycetes, order Saccharomycetales, and family Dipodascaceae (de Hoog, 2004). Specimens have been isolated from environmental sources and from human respiratory and gastrointestinal tracts. Rarely pathogenic in humans, *S. capitata* infection appears to occur more frequently than *S. clavata*. However, it is unclear if this observation is due to differences in pathogenicity or difficulty in discriminating at the species level.

Clinical presentation

The first case of invasive *S. capitata* was described in 1989 in a patient with acute myeloid leukemia (Mahul *et al.*, 1989). Since that time, hematologic malignancy and prolonged neutropenia have been recognized as the primary risk factors for disseminated Saprochaete infection (Bansal *et al.*, 2018; Ozdemir *et al.*, 2017; Trovato *et al.*, 2018). Upwards of 90% of infections occur in neutropenic patients with underlying hematologic malignancy. In one multicenter epidemiologic study, *Saprochaete* accounted for 1.7% of invasive fungal infections in immunocompromised hosts (Cornely *et al.*, 2015). Interestingly, most infections have occurred in Europe, but whether this is a result of true geographical distribution or bias in reporting is unknown. Fungemia is commonly reported, and is often associated with deep space infection involving the lungs, liver, spleen, central nervous system, or kidneys. Occasionally, skin lesions may manifest in a manner similar to disseminated candidiasis (Duran Graeff *et al.*, 2017). Both *S. capitata* and *S. clavata* have been associated with nosocomial disease. For instance, a nosocomial outbreak of *S. capitata* was described in association with contaminated vacuum flasks for milk delivery in a Spanish hospital (Gurgui *et al.*, 2011).

While most commonly afflicting those with hematologic malignancy, cases of fungemia, meningitis, endocarditis, and pneumonia have been reported in immunocompetent individuals (Cavanna *et al.*, 2017; Tanabe and Patel, 2018).

Diagnosis and identification

Invasive disease is diagnosed by recovery of *Saprochaete* species from blood or another sterile body fluid. The fungi forms colonies rapidly with maturation in culture over five days. Colonies appear white to cream colored, with formation of short aerial hyphae. Microscopically, true hyphae, pseudohyphae, annelloconidia, arthroconidia, and blastoconidia can be seen (Martino *et al.*, 1990). Careful attention must be made to avoid morphologic confusion with *Trichosporon* species or *Candida krusei* which may appear similarly, but have different susceptibility profiles. While the genus can be distinguished from *Trichosporon* by its urease negativity, biochemical testing is not reliable for species identification. Both MALDI-TOF-MS and sequencing of the internal transcribed spacer can discriminate *S. capitata* and *S. clavata* (de Almeida *et al.*, 2016; Desnos-Ollivier *et al.*, 2014). Distinction at species level is important, as *S. capitata* and *S. clavata* have differing *in vitro* susceptibility profiles. Cross-reactivity may occur with the *Aspergillus* galactomannan antigen and with β -1,3-D-glucan testing, but clinical experience with serologic testing is negligible and negative results should not be used to exclude disease (Giacchino *et al.*, 2006; Odabasi *et al.*, 2006).

Therapy and outcomes

There are no standardized interpretive criteria for determining antifungal susceptibility for *Saprochaete* infections. European guidelines currently recommend amphotericin B alone or in combination with flucytosine as first-line therapy, with voriconazole as an acceptable alternative (Arendrup *et al.*, 2014). This is based upon *in vitro* susceptibility data along with limited clinical experience from case reports and case series. *In vitro*, amphotericin B MICs are moderate, while flucytosine MICs are consistently low. However, as most infected patients are neutropenic, clinicians may be reluctant to use flucytosine due to risk of bone marrow toxicity. *S. capitata* MICs to itraconazole, posaconazole, and voriconazole are low. Various studies of MIC testing for isavuconazole are disparate with MICs ranging widely. In contrast, fluconazole MICs are consistently elevated (Guinea *et al.*, 2010). While *Saprochaete* are intrinsically resistant to echinocandins, combination therapy with voriconazole has been utilized due to a potential *in vitro* synergy (Etienne *et al.*, 2008; Fianchi *et al.*, 2008). Break-through infections have unsurprisingly occurred on echinocandin prophylaxis, but have been reported on prophylaxis with fluconazole, posaconazole, and amphotericin B as well (Bansal *et al.*, 2018; Chittick *et al.*, 2009; Schuermans *et al.*, 2011).

In addition to antifungal therapy, early catheter removal may improve survival. Granulocyte infusions and interferon-gamma administration in combination with antifungal therapy has also been described with success in one neutropenic patient (Favre *et al.*, 2016).

Outcomes in disseminated *Saprochaete* disease are generally poor, with thirty-day mortality ranging from 39% to 90% in various retrospective reviews of neutropenic patients (Vaux *et al.*, 2014). In immunocompetent patients, mortality rates are significantly lower, suggesting survival depends significantly on recovery of the host's immune function.

Trichosporon and Cutaneotrichosporon Species

Introduction

In contrast to members of the *Saprochaete* genus, *Trichosporon* species are anamorphic, non-fermentative, urease-positive basidiomycetous yeasts (Agaricomycotina, Tremellomycetes, Tremellales, Trichosporonaceae). They are ubiquitous throughout temperate and tropical environments, and are estimated to colonize mucosal surfaces of around 1%–10% of the healthy human population (Haupt *et al.*, 1983; Messias Silvestre *et al.*, 2010). First identified as a cause of superficial mycosis in the 1860s, *Trichosporon* species form a complex group of fungi, previously all classified as *T. beigeli*. Advanced biochemical and molecular techniques have shed light on the heterogeneity of the genus, resulting in several revisions of the taxonomic classification (Liu *et al.*, 2015), with some members now classified under the genus *Cutaneotrichosporon*. Currently, over 50 species of *Trichosporon* and *Cutaneotrichosporon* have been identified, with six significant species causing disease in humans: *T. asahii*, *T. asteroides*, *T. ovoides*, *C. mucoides*, *C. inkin*, and *C. cutaneum*. A seventh species, *Cutaneotrichosporon mycotoxinivorans* has been increasingly reported in association with pulmonary colonization and infection in patients with cystic fibrosis (Hickey *et al.*, 2009).

Clinical presentation

Infections caused by members of the *Trichosporon* and *Cutaneotrichosporon* genera range from superficial infection to invasive and disseminated disease, often depending upon underlying host immunity.

Superficial infection, occasionally referred to as trichosporosis or white piedra, occurs as infection of the hair follicles. The scalp, eyebrows, mustache, beard, axillary and genital hairs may all be involved. White piedra disproportionately affects those of all ages living in tropical climates, although cases in temperate climates may occur. Socioeconomic status and hygiene are not known risk factors. *C. inkin*, *C. cutaneum*, and *T. ovoides* are the predominant pathogens causing superficial infections (Bonifaz *et al.*, 2019; Douchet *et al.*, 1994; Shivaprakash *et al.*, 2011).

Conversely, *T. asahii*, *T. asteroides*, and *C. mucoides* are most frequently implicated in systemic or disseminated infections. Predominant underlying patient risk factors are the presence of hematologic malignancy and neutropenia. Other risk factors include prior corticosteroid use, organ transplantation, HIV/AIDS, and intravenous drug use. Disseminated trichosporonosis

was first reported in 1970 in a patient with metastatic lung adenocarcinoma (Watson and Kallichurum, 1970). Since then, over 300 cases have been documented in the medical literature including fungemia, pneumonia (Ruan *et al.*, 2009), peritonitis, endophthalmitis (Chakrabarti *et al.*, 2008; Scofield-Kaplan *et al.*, 2018), meningitis (Kumar *et al.*, 2015), esophagitis (Lo Passo *et al.*, 2001; Macedo *et al.*, 2011), and hepatosplenic abscesses. In mouse models, *Trichosporon* disseminates quickly with a propensity to infect the brain, heart, kidneys, lungs and liver (Hospenthal *et al.*, 1993; Montoya *et al.*, 2018). Dissemination is believed to occur by translocation across disrupted mucosal barriers during periods of mucositis and neutropenia. Virulence factors and pathogenicity among *Trichosporon* species causing invasive disease remains unknown (Colombo *et al.*, 2011).

Interestingly, *C. cutaneum* has been associated with summer-type hypersensitivity pneumonitis. However, this phenomenon has been identified only in Japan, and not observed elsewhere (Shimazu *et al.*, 1984; Yoshida *et al.*, 1989; Yoshida *et al.*, 1988). *T. mycotoxinivorans* is unique among *Trichosporon* species in causing pulmonary disease in patients with cystic fibrosis. Initially reported in 2009 as a case of fatal pneumonia (Hickey *et al.*, 2009), it has since been described in eight additional cases with variable clinical courses (Dabas *et al.*, 2017; Shah *et al.*, 2014a). However, the clinical significance of a positive respiratory culture for this yeast from cystic fibrosis patients remains unclear.

Diagnosis and identification

Trichosporon species grow easily on standard bacterial culture media and Sabouraud agar, and isolation in culture from a sterile body site or visualization on tissue histopathology is required for diagnosis. Isolation from mucosal sites may occur, and culture from these sites should prompt thorough clinical evaluation to distinguish colonization from infection. Rapidly growing, colonies initially appear smooth and cream-colored, but wrinkle and gray with age. Since the yeasts transform to mold *in vitro*, the presence of septate, hyaline hyphae with production of arthroconidia should prompt consideration of *Trichosporon*. While *Saprochaete* species also form arthroconidia, the two genera can be distinguished by urease testing and the absence or presence of annelloconidia. Biochemical testing can determine *Trichosporon* to the genus level, but is unreliable in species identification. Both genetic sequencing of the ITS region, and increasingly, MALDI-TOF-MS are useful modalities for determining species level identity (de Almeida Junior *et al.*, 2014; Kolečka *et al.*, 2013; Li *et al.*, 2005; Marklein *et al.*, 2009).

Cross reactivity with the cryptococcal polysaccharide latex agglutination assay has been reported in cases of trichosporonosis, due to presence of glucuronoxylomannan in the cell wall of *Trichosporon* species (Lyman *et al.*, 1995; Melcher *et al.*, 1991). However, this finding is not sensitive, and should not be used to exclude diagnosis of invasive disease.

Therapy and outcomes

Treatment of *Trichosporon* infection depends upon the extent of disease and underlying host immune function. White piedra can be treated with shaving of infected hair, followed by topical antifungal therapy, often ketoconazole shampoo daily for several months. Systemic *Trichosporon* infection is considerably more difficult to manage and portends a very poor prognosis, with reported mortality rates as high as 90% (Chagas-Neto *et al.*, 2009; Kontoyiannis *et al.*, 2004; Suzuki *et al.*, 2010).

In vitro susceptibility testing and case series reports suggest extended-spectrum azoles as therapies of choice. Testing of voriconazole and posaconazole against isolates reliably reproduce MIC values which suggest clinical efficacy (Araujo Ribeiro *et al.*, 2008; Chagas-Neto *et al.*, 2009). Fluconazole MICs range very widely, but fluconazole monotherapy was used successfully in a small series of Taiwanese patients with a 42% mortality (Ruan *et al.*, 2009). Documented MIC values for amphotericin B against various *Trichosporon* species are generally too high for achievable serum concentrations at conventional dosing (Chagas-Neto *et al.*, 2009; Rodriguez-Tudela *et al.*, 2005). Furthermore, clinical response rates in patients treated with amphotericin B hover around 25% (Girmenia *et al.*, 2005). Echinocandins have little to no activity against *Trichosporon*, should not be used as monotherapy for trichosporonosis, and breakthrough infections have been reported (Kimura *et al.*, 2018; Matsue *et al.*, 2006). However, *in vitro* data exist to suggest a synergistic effect of echinocandins with both amphotericin B and azoles, and several case reports document successful combination therapy (Li *et al.*, 2011b; Serena *et al.*, 2005). Based upon currently available data, most clinicians would utilize voriconazole for treatment of trichosporonosis (Arendrup *et al.*, 2014). While antifungal therapy is imperative for treatment of invasive *Trichosporon*, successful treatment appears to depend primarily upon resolution of neutropenia and reconstitution of host immunity.

Phaeohyphomycosis

Introduction

Phaeohyphomycosis, a term derived from the Greek *phaeo-* (dusky) and *hypho-* (hyphal), is a broad clinical term that refers to a variety of infections caused by a myriad of molds which are identified by brown-black coloration of their vegetative state (Ajello *et al.*, 1974). This feature is caused by deposition of melanin within the cell wall of these pathogens, which are also known as dematiaceous fungi. Over 100 different fungal species are included as dematiaceous fungi, and reported to cause disease in humans at varying frequencies. They range widely through the taxonomy of the Fungi Kingdom, and are found within the Ascomycota, Basidiomycota, and Zygomycota phyla. This section will touch upon the clinical presentations of the more commonly seen species which comprise the phaeohyphomycoses.

Clinical Manifestations

Dematiaceous fungi cause a wide spectrum of disease in human hosts, ranging from asymptomatic colonization to life-threatening and devastating disseminated infection. Profoundly immunocompromised individuals, such as those with hematologic malignancy, solid organ or bone marrow transplant recipients, are at greatest risk of infection with this group of fungi; however, cases of phaeohyphomycosis have also been reported in apparently immunocompetent individuals. These pathogens are ubiquitous within the environment, and infection most frequently occurs by direct inoculation of the fungus, through trauma or medical procedures, or from inhalation of spores into the sinuses and respiratory tracts. Pathogens are generally implicated in certain clinical syndromes and treatment may vary depending upon the specific fungus isolated.

Cutaneous phaeohyphomycosis

All dematiaceous molds are capable of causing cutaneous disease, such as dermatomycosis or onychomycosis. Treatment with debridement of involved tissue or short courses of antifungal agents is typically sufficient for eradication in all but the most immunosuppressed individuals.

Subcutaneous phaeohyphomycosis

Subcutaneous disease is a common manifestation of phaeohyphomycosis, frequently caused by *Curvularia*, *Exophiala*, and *Phialophora* species. Symptoms include development of subcutaneous cysts and/or ulcerations, with or without satellite lesions. In immunocompetent persons, lesions may persist unchanged for years without treatment.

Keratitis

Most often fungal keratitis is caused by a traumatic injury to the cornea, either from accidental harm or surgical injury. Among the dematiaceous molds, *Curvularia*, *Exophiala*, and *Exserohilum* are commonly implicated. The hyalohyphomycoses, such as *Aspergillus*, *Fusarium*, and *Purpureocillium* (*Paecilomyces*) frequently cause keratitis and will be discussed later in this chapter.

Fungal sinusitis

Fungal sinusitis manifests in three predominant forms – allergic fungal sinusitis, eumycetoma, and invasive sinusitis. The first two are localized diseases without tissue invasion that produce a local eosinophilic response, and are often managed surgically. Conversely, invasive fungal sinusitis is an aggressive disease characterized by bony destruction, which may progress intracranially if left unchecked. Of the dematiaceous molds, *Alternaria* and *Curvularia* species are often involved. Other fungi producing similar disease include *Aspergillus* and the mucormycoses, discussed elsewhere.

Disseminated phaeohyphomycosis

Disseminated infection implies systemic disease from an inoculating injury, such as inhalation through the respiratory tract or penetration through the skin. Patients are most commonly immunosuppressed, either following transplantation, or secondary to profound neutropenia from hematologic malignancy or chemotherapy. Several species are known for their neurotropism and propensity to cause brain abscesses, such as *Cladophialophora bantiana*, *Exophiala* (*Wangiella*) *dermatiditis*, *Ochroconis gallopava*, and *Rhinocladiella mackenziei*. Others, such as *Lomentospora prolificans* cause fungemia and/or pulmonary disease in immunocompromised hosts.

Common Species Causing Phaeohyphomycosis

Alternaria species

The genus *Alternaria* includes over 100 species, of which two – *A. infectoria* and *A. alternata* – form the near totality of human infection. The predominant syndromes caused by *Alternaria* species are cutaneous and subcutaneous phaeohyphomycosis (Ferrandiz-Pulido *et al.*, 2019), although fungal sinusitis (Pesci *et al.*, 2015), ocular keratitis, onychomycosis (Arrese *et al.*, 1996), and disseminated disease (Mirhendi *et al.*, 2013) also occur. The most common risk factors for developing disease are hematologic malignancy with neutropenia, and solid organ or hematologic transplantation. Cutaneous and ocular disease typically results following a traumatic or surgical inoculation, resulting in either localized soft tissue infection or keratitis, respectively.

Culture of *Alternaria* is most effectively realized on potato-carrot agar. Morphologically, *A. infectoria* and *A. alternata* form septate, melanized hyphae, and may be distinguishable by their conidia formations. *A. alternata* conidia demonstrate multiple, branching, cylindrical beaks, whereas *A. infectoria* displays scarce, tubular conidia with secondary long, multiseptated conidiophores (Pastor and Guarro, 2008). Reliable species identification is made through sequencing of the ITS region, with particular attention to the length of the ITS-4 amplicon (de Hoog and Horre, 2002; Leahy *et al.*, 2010). Experience with mass spectrometry for identification of *Alternaria* at the genus and species level is limited and not yet validated for clinical microbiology (Panda *et al.*, 2015).

In vitro susceptibility testing of *Alternaria* isolates is minimal. Data that exists suggests resistance to flucytosine and fluconazole, and a wide range of MICs to amphotericin B (Pujol *et al.*, 2000). Itraconazole, voriconazole, and posaconazole demonstrate excellent *in vitro* antifungal activity against *Alternaria* (Cuenca-Estrella *et al.*, 2006). Clinical experience with

itraconazole is greatest, but increasing reports of success with posaconazole (Lyskova *et al.*, 2017) will likely make it a first-line drug for treatment of this fungus.

In addition to antifungal therapy, surgical management and withdrawal of immunosuppression, if possible, is recommended for invasive disease. Localized cutaneous disease may be cured with surgical management alone. Outcomes for alternariosis appear to be rather good, with relatively low mortality, likely due to its predilection to cause localized cutaneous disease without dissemination.

Bipolaris species

Three fungi formerly belonging to the genus *Bipolaris* are known to cause human disease – *B. australiensis*, *B. hawaiiensis*, and *B. spicifera*. These molds have recently been reclassified under the genus *Curvularia* based upon sequencing of the internal transcribed spacer and GPDH rDNA (Manamgoda *et al.*, 2012).

Cladophialophora species

Cladophialophora bantiana (previously classified as *Cladosporium bantianum*, *Xylohypha bantiana*, or *Torula bantiana*) is the major pathogenic mold of this genus, and the leading cause of cerebral phaeohyphomycosis. It has also been reported to cause pulmonary phaeohyphomycosis, although pulmonary colonization has not been associated with increased risk of central nervous system disease. In a large review of clinical cases, many patients had no identifiable underlying risk factor; however, a large plurality of individuals had undergone solid organ transplantation or received prolonged courses of corticosteroids (Kantarcioglu *et al.*, 2017).

Cerebral phaeohyphomycosis should be suspected in patients with imaging suggestive of intracranial abscess, and indolent symptoms of increased intracranial pressure (headaches, altered mentation, seizures) in the absence of fever. There are no specific findings for cerebral phaeohyphomycosis, and the differential diagnosis will commonly include malignancy and other infectious etiologies. Meningitis may also occur with or without brain abscess. Diagnosis is made by isolation of *C. bantiana* in culture or detection of hyphae on histopathology.

In clinical culture *Cladophialophora* grows as a mold with long, branching, hydrophobic conidia seen microscopically. Identification is most accurately made by sequencing the rDNA of the ITS region (Abliz *et al.*, 2004; Caligiorno *et al.*, 2005). Mass spectrometry is not yet reliable for identification of *Cladophialophora* due to deficiencies in the existing commercial databases (Singh *et al.*, 2017).

Treatment of cerebral phaeohyphomycosis caused by *C. bantiana* necessitates surgical excision/debulking and antifungal therapy. In the absence of these interventions, infection is uniformly fatal. Unfortunately, mortality still hovers around 70%, even with surgery and antifungal medications, regardless of the immune status of the patient (Kantarcioglu *et al.*, 2017). *In vitro* susceptibility data suggest good antifungal activity of itraconazole and posaconazole (Badali *et al.*, 2010). While voriconazole MICs are higher, voriconazole demonstrates higher oral bioavailability and central nervous system penetration than either itraconazole or posaconazole. Conversely, while amphotericin B MICs are low, CNS penetration is poor, likely limiting efficacy (Al-Abdely *et al.*, 2005). In mouse models, combination therapy with flucytosine, micafungin and posaconazole prolonged survival time over controls, single and double combination therapies (Marine *et al.*, 2009).

Other species of *Cladophialophora* are implicated in human disease. *C. carrionii* is a frequent cause of chromoblastomycosis with a similar drug susceptibility profile to *C. bantiana* (Deng *et al.*, 2013). Other infrequently reported causes of disseminated phaeohyphomycosis include *C. arxii* and *C. devriesii* (Mitchell *et al.*, 1990; Tintelnot *et al.*, 1995).

Curvularia species

There are over 100 species within the *Curvularia* genus, but only a few are known to cause disease in humans. The predominant pathogens are *C. aeria*, *C. lunata* and *C. geniculata*. As mentioned above, several clinically relevant *Bipolaris* species have recently been reclassified as *Curvularia* species: *C. australiensis*, *C. hawaiiensis*, and *C. spicifera* (Manamgoda *et al.*, 2012).

The most common clinical syndrome caused by *Curvularia* species is allergic fungal rhinosinusitis (Nishioka *et al.*, 1987), but invasive fungal sinusitis has also been documented (Ebright *et al.*, 1999). Brain abscess (Gadgil *et al.*, 2013; Gonzales Zamora and Varadarajalu, 2019; Skovrlj *et al.*, 2014), endocarditis (Kaufman, 1971), endophthalmitis (Berbel *et al.*, 2011; Pathengay *et al.*, 2012), keratitis (Dorey *et al.*, 1997), mycetoma (Gunathilake *et al.*, 2014; Janaki *et al.*, 1999), peritonitis (Subramanyam *et al.*, 2016; Ujhelyi *et al.*, 1990), and disseminated disease (Vasikasin *et al.*, 2019; Rohwedder *et al.*, 1979) have also been reported.

Colonies of *Curvularia* grow rapidly and are characterized by brown or black-brown pigment, like other dematiaceae fungi. Conidia appear curved or lunate, with rounded ends and usually three to five septa. *Curvularia* cannot be reliably distinguished from *Bipolaris* morphologically, and sequencing of the glyceraldehyde-3-phosphate dehydrogenase gene is needed to accurately determine isolates at the species level (Jeon *et al.*, 2015).

Treatment of allergic fungal sinusitis is primarily achieved by surgical resection and oral corticosteroid therapy. Antifungal therapy has not been shown to be effective (Schubert, 2009), although occasionally itraconazole or amphotericin B are administered. Invasive or systemic disease necessitates antifungal therapy. Amphotericin B seems to have the most *in vitro* activity (da Cunha *et al.*, 2013). While MICs for the triazoles are generally higher, posaconazole and itraconazole likely retain some efficacy. There is no standard therapy for invasive *Curvularia* infection, but amphotericin B and azoles are typically utilized to varying degrees of success (Gonzales Zamora and Varadarajalu, 2019; Kalawat *et al.*, 2012; Moody *et al.*, 2012).

Exophiala species

Exophiala (Wangiella) counts over forty species in the genus, with a handful causing disease in human hosts. The pathogenic species are *E. dermatitidis*, *E. xenobiotica*, *E. oligosperma*, *E. lecaniicorni*, *E. phaeomuriformis*, *E. jeanselmi*, *E. bergeri*, and *E. mesophila*, listed in order of clinically observed frequency (Zeng et al., 2007). Ubiquitous in the nature, *Exophiala* species have been primarily isolated from warm, humid environments (Babic et al., 2018).

The most commonly seen infections caused by *Exophiala* species are cutaneous and subcutaneous phaeohyphomycosis. However, *Exophiala* displays a significant neurotropism – as do other members of the order Chaetothyriales – and *E. dermatitidis* commonly causes cerebral phaeohyphomycosis, almost exclusively in Asian countries (Li et al., 2011a). The reason for this geographical preference is not well understood, but speculation has been given to potential increased inoculum exposure. Infections occur in both immunocompromised and immunocompetent individuals, with dissemination more frequent in those with impaired immunity. Fungemia is a rare event, although an outbreak of *E. dermatitidis* fungemia was described in oncologic patients in New York who received treatment with a contaminated IV flush solution (Vasquez et al., 2018). Other reported infections caused by *Exophiala* include cases of pneumonia (Cohen and Stead, 2015; Suzuki et al., 2012), endocarditis (Berger et al., 2017; Patel et al., 2013), peritonitis (Agarwal et al., 1993; Lau et al., 2003; Pinheiro et al., 2019) and endophthalmitis (Clamp et al., 2014; Homa et al., 2018). While not representing infection, *Exophiala* species commonly colonize the respiratory tracts of patients with cystic fibrosis (Lebecque et al., 2010).

Members of the genus are slowly growing dematiaceous fungi, which are best cultivated on selective agars, such as erythritol-chloramphenicol agar. In culture, colonies appear restricted, waxy and smooth. Initial growth appears yeast-like, but with maturation, cells thicken and darken, developing mycelium with cylindrical annellides. Conidia appear pale brown and accumulate at the ends of annellides. Species identification is best performed by gene sequencing of the ITS region (Nagano et al., 2008), although mass spectrometry can also reliably differentiate species of *Exophiala* (Borman et al., 2017).

In cases of cutaneous phaeohyphomycosis with *Exophiala*, surgical intervention may be curative. More invasive disease often necessitates combined surgical resection, if possible, and antifungal therapeutics. Posaconazole, voriconazole, itraconazole and isavuconazole all demonstrate activity against *Exophiala* species in *in vitro* assays (Fothergill et al., 2009; Gonzalez, 2009). Most strains also appear susceptible to amphotericin B; however, an experimental mouse model suggests increased efficacy of posaconazole over amphotericin B in disseminated disease due to *Exophiala dermatitidis* (Calvo et al., 2010). Echinocandins have little-to-no activity against *Exophiala* and breakthrough infections in patients on echinocandin prophylaxis are documented (Watanabe et al., 2018). Human clinical experience is greatest with amphotericin B, posaconazole and voriconazole, all of which have been used successfully in case reports (Nachman et al., 1996; Negroni et al., 2004; Saito et al., 2018; Vasquez et al., 2018). For cerebral phaeohyphomycosis, current guideline-directed therapy consists of complete excision, or at least substantial debulking, coupled with voriconazole or posaconazole, with combination therapy considered in cases where surgical management is not possible (Chowdhary et al., 2014).

Exserohilum rostratum

While there are over 30 species of fungi belonging to the genus *Exserohilum*, only *E. rostratum* is known to cause disease in humans. *E. longirostratum* and *E. mcginnisii* are reported in older medical literature as pathogenic species, but have since been found to be identical to *E. rostratum* on the basis of molecular sequencing (da Cunha et al., 2012). An environmental fungus, found commonly in soil, *E. rostratum* is a rare cause of allergic or invasive fungal sinusitis; however, a large nosocomial outbreak of *Exserohilum rostratum* CNS infections occurred in the United States in 2012 due to a contaminated methylprednisolone supply (Smith et al., 2013).

Exserohilum are closely related to the genera *Bipolaris* and *Curvularia*. Therefore, morphologies seen among these species are quite similar. Isolates form dark brown colonies, with aerial mycelium which appear wooly. Conidia are ellipsoidal, straight to slightly bent, and septate, with protruding hilum (Sharma et al., 2014). Accurate species level identification is made by sequencing of the ITS region (da Cunha et al., 2012). Mass spectrometry identification has not been proven for *Exserohilum* species.

Amphotericin B, followed by ketoconazole, has most often been used for therapy of invasive respiratory disease. The treatment of choice during the fungal meningitis outbreak caused by *Exserohilum* was voriconazole, owing primarily to its pharmacologic property of high central nervous system penetration (Kainer et al., 2012). In *in vitro* studies, posaconazole, itraconazole and voriconazole display low MIC values, while isavuconazole MICs are notably higher (Chowdhary et al., 2015). Echinocandin MICs vary widely and breakthrough cases have been reported (Chou et al., 2007). Current expert opinion suggests treatment with amphotericin B alone or in combination with an azole for systemic disease, and voriconazole monotherapy for central nervous system disease (Pappas et al., 2013).

Lomentospora prolificans

Classically, this species was included in the hyalohyphomycoses with other *Scedosporium* species; however, *L. prolificans* often exhibits melanized hyphae, a defining trait of the phaeohyphomycoses. Furthermore, *Lomentospora prolificans* (formerly *Scedosporium prolificans* or *S. inflatum*) was reclassified into its own genus on the basis of tubulin molecular sequencing (Lackner et al., 2014a). To further contrast with *Scedosporium apiospermum*, it is rarely isolated from environmental sources, and appears geographically restricted, with most cases reported in Australia, Spain and the United States (Rodriguez-Tudela et al., 2009; Seidel et al., 2019).

Clinically, disease from *L. prolificans* ranges from asymptomatic colonization to disseminated, devastating, and often fatal, disease. Pulmonary colonization is well described and occurs in individuals with underlying cavitory or bronchiectatic disease, such as those living with cystic fibrosis (Sedlacek *et al.*, 2015). In immunocompetent patients, the most common disease entity encountered is localized cutaneous or subcutaneous disease, resulting from traumatic inoculation (Steinbach *et al.*, 2003). Invasive infection is seen in patients with profound immunosuppression, most often in individuals with hematologic malignancy and prolonged neutropenia, hematopoietic stem cell transplant recipients, or in patients after solid organ transplantation receiving alemtuzumab or anti-thymocyte globulin induction. When disseminated disease does occur, the lungs, central nervous system, eye, and heart are often involved, and blood cultures are frequently positive (Seidel *et al.*, 2019).

Diagnosis of *Lomentospora* infection is made by isolation of the organism in culture or visualization on histopathology. Isolation in culture is more readily achieved preventing overgrowth by *Aspergillus* species by use of a selective media, SceSel⁺, which contains dichloran and benomyl (Rainer *et al.*, 2008). Differentiation of *L. prolificans* from *Scedosporium* species can easily be made by observation of morphologic and phenotypic characteristics. *L. prolificans* forms darkly pigmented colonies, is susceptible to cycloheximide, and displays flask-shaped conidiogenous cells. As noted previously, molecular sequencing of the ITS region can identify species within the *Scedosporium/Lomentospora* complex, with further sequencing of the tubulin gene allowing for species differentiation (Lackner *et al.*, 2014a). Mass spectrometry has been shown to be as effective as molecular testing for identification of clinical isolates to a species level (Coulibaly *et al.*, 2011; Sitterle *et al.*, 2014; Sleiman *et al.*, 2016).

Treatment of *Lomentospora* is problematic, due to its resistance to nearly all available antifungal therapy. Clinical isolates are resistant to amphotericin B, echinocandins, fluconazole, isavuconazole, posaconazole and flucytosine, and demonstrate variably high MICs to voriconazole and itraconazole (Castanheira *et al.*, 2012; Cuenca-Estrella *et al.*, 1999; Guinea *et al.*, 2008). Some combination therapies, such as voriconazole and micafungin (Heyn *et al.*, 2005), or terbinafine and itraconazole (Meletiadiadis *et al.*, 2000) have shown *in vitro* synergism. A murine model has demonstrated prolonged survival time and decreased fungal burden in mice treated with the combination of micafungin and voriconazole or amphotericin B (Rodriguez *et al.*, 2009). More recently, several investigational drugs have shown promise in combating *Lomentospora* infection. APX001 (fosfomanogepix), a novel antifungal acting against Gwt1p, a protein critical for cell wall integrity, displays low MIC values when tested against *L. prolificans* (Rivero-Menendez *et al.*, 2019). Similarly, F901318 (olorofim), a dihydroorotate dehydrogenase inhibitor, has shown promising *in vitro* activity against clinical isolates (Biswas *et al.*, 2018; Wiederhold *et al.*, 2017).

Voriconazole therapy is most commonly utilized clinically due to its relatively lower MIC values. A review of 56 cases of invasive *Lomentospora* infection found that mortality rates were diminished with voriconazole therapy, but that combination with terbinafine did not further improve survival (Seidel *et al.*, 2019). However, on the basis of previously published case reports, most recent current European guidelines modestly recommend combination voriconazole and terbinafine therapy (Tortorano *et al.*, 2014). Surgical debridement of involved tissue and restoration of immune function are critical to improving outcomes of *Lomentospora* infection. Unfortunately, mortality from *Lomentospora* infection remains extremely high, with around 70%–80% of patients ultimately succumbing to their disease.

Hyalohyphomycoses

The hyalohyphomycetes constitute a diverse group of molds which are characterized by their lack of melanin deposition within the fungal cell wall (Ajello, 1986). This finding primarily distinguishes them from the phaeohyphomycetes, or dematiaceous molds, which were addressed previously within this chapter. Clinically encountered hyaline molds include *Aspergillus* (discussed elsewhere in this book), and *Fusarium*, *Purpureocillium* (*Paecilomyces*), *Scedosporium*, and *Scopulariopsis*, which will be touched upon here.

Fusarium

Predominantly phytopathogens, over 300 species of *Fusarium* have been identified, with over 20 identified as agents of human infection (Balajee *et al.*, 2009). Behind *Aspergillus* species, *Fusarium* species are the second most common cause of hyalohyphomycosis in certain patient populations (Marr *et al.*, 2002). Phylogenetic analyses have shown that many *Fusarium* species can be classified as a species complex (Summerell, 2019). In human disease, four complexes appear to predominate: *Fusarium solani* species complex (*F. solani* sensu stricto, *F. keratoplasticum*, *F. falciforme*, *F. petroliphilum*), *Fusarium oxysporum* species complex (*F. oxysporum*), *Fusarium fujikuroi* species complex (*F. verticillioides*, *F. proliferatum*, *F. acutatum*), and *Fusarium dimerum* species complex (*F. dimerum*, *F. delphinoides*) (Muraosa *et al.*, 2017). *F. solani* and *F. verticillioides* comprise a plurality to majority of infections due to *Fusarium* species (Tortorano *et al.*, 2008). Infections occur in immunocompetent and immunocompromised hosts, but hematopoietic stem cell transplant recipients suffer from significantly increased risk (Nucci *et al.*, 2004).

Clinical disease caused by *Fusarium* species runs the gamut from localized skin and soft tissue infection to disseminated disease with fungemia. *Fusarium solani* is the most common cause of fungal keratitis, often occurring in tropical climates after traumatic injury (Cheikhrouhou *et al.*, 2014). Ocular infection has also been associated with contact lens use, including a worldwide outbreak from 2005 to 2006 related to use of an ineffectively fungistatic cleaning solution (Chang *et al.*, 2006; Khor *et al.*, 2006). Cases can result in permanent visual impairment by contiguous spread into the posterior chamber, resulting in endophthalmitis, a particularly feared complication. Skin and soft tissue infections include onychomycosis,

eumycetoma and colonization and infection of burn injuries. Importantly, individuals with hematologic malignancy are at increased risk of invasive fusariosis if *Fusarium* species are cultured from preexisting skin lesions (Varon *et al.*, 2014). Invasive fusariosis is most frequently seen in patients with acute leukemia or hematopoietic stem cell transplant patients, particularly patients having undergone mismatched allogeneic transplantation (Atalla *et al.*, 2015; Nucci *et al.*, 2004). In these patients, infection most often manifests as sinopulmonary disease, localized deep-seated infection, disseminated fusariosis, or fever of unknown origin. Clinically, fusariosis is difficult to distinguish from invasive aspergillosis, but some key distinctions may be seen. In pulmonary disease, CT imaging cannot reliably distinguish between aspergillosis and fusariosis; however, absence of the halo sign or occluded vessel sign suggest a *Fusarium* etiology (Sassi *et al.*, 2017). Additionally, patients with disseminated fusariosis often have positive blood cultures and skin manifestations, which are uncommonly seen in invasive aspergillosis (Bodey *et al.*, 2002; Nucci *et al.*, 2018; Torres *et al.*, 2003). Notably, serum *Aspergillus* antigenemia is not reliable for distinguishing between *Aspergillus* and *Fusarium* as there is significant cross-reactivity between these genera (Fernandez-Cruz *et al.*, 2019; Horn *et al.*, 2014; Nucci *et al.*, 2018; Tortorano *et al.*, 2012). *Fusarium* infections have been reported in cases of septic arthritis (Stempel *et al.*, 2015), endocarditis (Guzman-Cottrill *et al.*, 2004; Jorens *et al.*, 1990; Kassir *et al.*, 2016; Nunes *et al.*, 2013), peritonitis (da Silva-Rocha *et al.*, 2015; Mayr *et al.*, 2017; Shah *et al.*, 2014b), brain abscess (Chen *et al.*, 2017).

Fusariosis may be diagnosed by histopathology or culture. On histopathology, acutely-angled, branching, septate hyphae are visualized, as is seen in invasive aspergillosis, without distinguishing features to discriminate between *Fusarium* and *Aspergillus*. Recently, a small, single center study showed promise in obtaining accurate species diagnosis through quantitative PCR of the ITS region in clinical samples in formalin-fixed, paraffin-embedded tissue (Salehi *et al.*, 2016). This method may be useful to aid in identification when culture results are not forthcoming.

As noted previously, blood cultures are frequently positive (70%–80%) in patients with disseminated fusariosis due to its ability to form adventitial, yeast-like forms in tissue (Liu *et al.*, 1998). *Fusarium* cultures develop rapidly and form white colonies with a pink to violet center and lighter periphery. Microscopically, macroconidia, microconidia and chlamydospores may be seen. The presence of macroconidia allows for identification of *Fusarium* at the genus level, as macroconidia form a characteristic canoe, or banana, shape. Otherwise, *Fusarium* species may be confused with other pathogenic fungi. Discrimination at the species level utilizing morphologic techniques is difficult, time-intensive, and unreliable. Instead, molecular sequencing of the RNA polymerase II RPB2 subunit and translation elongation factor 1- α allow for accurate identification to a species level (Thomas *et al.*, 2019; van Diepeningen *et al.*, 2015). Mass spectrometry, through MALDI-TOF methods, are also increasingly reliable in identifying *Fusarium* species correctly, especially as databases improve (De Carolis *et al.*, 2012; Sleiman *et al.*, 2016; Triest *et al.*, 2015).

Fusarium species are intrinsically resistant to most antifungal agents, including flucytosine, miconazole, ketoconazole, itraconazole, fluconazole, and the echinocandins (Arikan *et al.*, 2001; Espinel-Ingroff, 2003; Pujol *et al.*, 1997; Reuben *et al.*, 1989; Speeleveid *et al.*, 1996). Among species, *F. solani* displays more resistance than other non-*solani* *Fusarium* species, including *F. verticillioides* and *F. oxysporum*, which retain some activity to voriconazole and posaconazole (Alastruey-Izquierdo *et al.*, 2008). Of the newer extended spectrum azoles, voriconazole, and posaconazole have variable, fungistatic activity against *Fusarium* species, whereas isavuconazole is ineffective in *in vitro* studies (Gonzalez, 2009; Guinea *et al.*, 2008). Amphotericin B and natamycin retain the most efficacy against clinical *Fusarium* isolates (Reuben *et al.*, 1989; Rotowa *et al.*, 1990). Due to the intrinsically resistant nature of *Fusarium*, combination antifungal therapy has been extensively studied *in vitro* and in animal models. One small *in vitro* study demonstrated no synergism between amphotericin B and voriconazole in *F. solani* and *F. oxysporum* isolates, but showed synergism with the combination of terbinafine and voriconazole (Cordoba *et al.*, 2008). Another *in vitro* study has shown synergism against *Fusarium* isolates with the combination of natamycin and voriconazole (Al-Hatmi *et al.*, 2016), while a third documented synergistic combinations of amphotericin B and ravuconazole, terbinafine and ravuconazole, and terbinafine and voriconazole (Ortoneda *et al.*, 2004). In a murine model, the combination of amphotericin B and voriconazole improved survival in a small cohort of mice infected with *F. solani*, although fungal burden was not decreased (Ruiz-Cendoya *et al.*, 2008).

Fusarium keratitis is often treated with topical natamycin, confirmed by the results of the Mycotic Ulcer Treatment Trial, which documented superior clinical outcomes with topical natamycin compared to topical voriconazole (Prajna *et al.*, 2013). In secondary analysis from the same study, individuals receiving adjunctive oral voriconazole were at decreased risk of corneal perforation or need for therapeutic penetrating keratoplasty (Prajna *et al.*, 2017). Onychomycosis is most often treated with terbinafine and voriconazole (Al-Hatmi *et al.*, 2018).

While mortality from invasive *Fusarium* infection remains high, clinical evidence suggests that utilization of high-dose voriconazole monotherapy or combination therapy with amphotericin B and voriconazole for treatment of fusariosis is increasingly practiced by physicians with improving survival (Jenks *et al.*, 2018; Nucci *et al.*, 2014). Indeed, current guidelines recommend combination therapy with liposomal amphotericin B and voriconazole as first-line therapy for invasive fusariosis (Tortorano *et al.*, 2014), along with surgical debridement and reversal of immunosuppression, if possible. Posaconazole is recommended as salvage therapy in patients failing first line therapy on the basis of small, uncontrolled clinical observations (Alexander *et al.*, 2008; Chowdhary *et al.*, 2014; Raad *et al.*, 2006). Studies have shown consistently poor outcomes in patients with persistent neutropenia (Fernandez-Cruz *et al.*, 2019; Nucci *et al.*, 2014; Nucci and Anaissie, 2007). On this fact, several investigators have evaluated the role of granulocyte transfusion and granulocyte colony-stimulating factor therapy as an adjunctive therapy in patients with invasive fusariosis (Kadri *et al.*, 2015). Despite the promise of adjunctive therapies, these studies remain clouded by confounders and the role of immune supplementation remains unclear.

Scedosporium

The genus *Scedosporium* (previously also *Pseudallescheria*) has undergone a major taxonomic revision in the last decade on the basis of phylogenetic analysis and simplification of nomenclature. As a result, currently 10 species of *Scedosporium* are recognized – *S. apiospermum*, *S. angustum*, *S. boydii*, *S. ellipsoideum*, and *S. fusoideum*, comprising the *S. apiospermum* species complex; and *S. aurantiacum*, *S. cereisporum*, *S. dehoogii*, *S. desertorium*, and *S. minutisporum* forming the remainder (Gilgado *et al.*, 2005, 2008; Lackner *et al.*, 2014a). Of these, *S. apiospermum* and *S. aurantiacum* are the most relevant agents of human disease. *Lomentospora prolificans* (formerly *S. prolificans* or *S. inflatum*) is no longer categorized with *Scedosporium* species and is discussed previously within this chapter.

Scedosporium species are ubiquitous having been cultured from agricultural soil, animal droppings, environmental water sources, and sewage (Rougeron *et al.*, 2018). Geographical differences exist, with *S. aurantiacum* far more commonly isolated in Australia, and *S. dehoogii* and *S. apiospermum* more frequently encountered in Europe (Harun *et al.*, 2010; Kaltseis *et al.*, 2009). Their omnipresence likely results in their frequent isolation from the respiratory tracts of patients with cystic fibrosis, where they are the second most common mold isolated, only trailing *Aspergillus* species (Cimon *et al.*, 2000; Engel *et al.*, 2019).

Infections with *Scedosporium* species affect both immunocompetent and immunocompromised hosts. In patients with intact immunity, traumatic inoculation results in most clinical manifestations and *Scedosporium* is a predominant cause of eumycetoma and fungal arthritis (Bonifaz *et al.*, 2014; Estrada *et al.*, 2012; Sampaio *et al.*, 2017; Tirado-Miranda *et al.*, 2001). *S. apiospermum*, *S. aurantiacum* and *S. boydii* have also precipitated fatal intracranial abscesses in victims of near-drowning events (Buzina *et al.*, 2006; Gari *et al.*, 1985; Katragkou *et al.*, 2007; Kowacs *et al.*, 2004). Furthermore, there are reports of fatal disseminated scedosporiosis following organ transplantation from nearly-drowned donors (Kim *et al.*, 2015; Leek *et al.*, 2016). Cases of keratitis (Saracli *et al.*, 2003a), peritonitis (Severo *et al.*, 1999), sinusitis (Loh *et al.*, 2018), and endocarditis (O'Bryan *et al.*, 2002) have also been documented in immunocompetent individuals.

Profoundly immunosuppressed individuals, including those with solid organ or hematopoietic stem cell transplants, as well as persons with the Acquired Immunodeficiency Syndrome, are at particularly increased risk of invasive and disseminated scedosporiosis. (Cortez *et al.*, 2008; Neofytos *et al.*, 2010; Tammer *et al.*, 2011). Neutropenia and receipt of T-cell depleting agents are also significant risk factors (Johnson *et al.*, 2014; Lamaris *et al.*, 2006). Disseminated scedosporiosis typically develops from haematogenous spread secondary to underlying pneumonia, and may result in fungemia (Husain *et al.*, 2005). Other presentations in immunocompromised hosts include intracranial abscess, endophthalmitis (Castiglioni *et al.*, 2002), meningitis and endocarditis (Uno *et al.*, 2014), and osteomyelitis (Ochiai *et al.*, 2003).

Diagnosis of *Scedosporium* infection requires isolation of fungi from a sterile body site or visualization of the mold by microscopic or histopathologic evaluation. In histopathology, *Scedosporium* cannot be readily distinguished from other hyalohyphomycetes, including *Aspergillus* or *Fusarium* species, however presence of hyphae branching at right angles and intravascular conidia may suggest the diagnosis (Kimura *et al.*, 2010). In culture, selective media such as SceSel⁺, which contains dichloran and benomyl, can help to recover *Scedosporium* from clinical samples (Rainer *et al.*, 2008). As mentioned previously, *Scedosporium* species can be distinguished from *Lomentospora prolificans* as the latter is susceptible to cycloheximide, and produces flask-shaped conidiogenous cells. To identify *Scedosporium* to a species level, molecular sequencing and mass spectrometry are clinically available and accurate (Coulibaly *et al.*, 2011; Sitterle *et al.*, 2014; Steinmann *et al.*, 2011; Lu *et al.*, 2011).

Treatment of *Scedosporium* infection is complicated by the lack of available therapeutic antifungal agents. Amphotericin B, flucytosine, fluconazole, itraconazole, and ketoconazole all display limited *in vitro* activity against *S. apiospermum* (Cuenca-Estrella *et al.*, 1999). The extended-spectrum azoles voriconazole and posaconazole retain variable activity against *S. apiospermum* isolates, with voriconazole demonstrating consistently lower MIC values when compared with posaconazole (Carrillo and Guarro, 2001; Lackner *et al.*, 2012; Meletiadis *et al.*, 2002). However, both antifungals have shown retained efficacy *in vivo* by decreasing fungal burden and prolonging survival in murine and guinea pig animal models (Capilla *et al.*, 2003; Capilla and Guarro, 2004; Rodríguez *et al.*, 2010). The newest triazole, isavuconazole, appears to be ineffective against all species of *Scedosporium*, based upon available MIC data (Guinea *et al.*, 2008; Lackner *et al.*, 2012). Echinocandins demonstrate significantly variable activity against *Scedosporium* species, and have been evaluated for synergism in combination with azole therapy. *In vitro* evaluation suggested possible synergism between voriconazole and micafungin (Heyn *et al.*, 2005). However, no survival benefit was seen with micafungin/voriconazole or micafungin/posaconazole combination therapy in an *in vivo* murine model (Lackner *et al.*, 2014b). Currently, recommended first-line therapy consists of voriconazole monotherapy for *S. apiospermum* infection. However, some clinicians would advocate for azole/polyene or azole/echinocandin combination therapy on the basis of case series (McCarthy *et al.*, 2018). At this time, two novel antifungal agents, APX001 (fosfomanogepix), and F901318 (olorofim) show promise for the treatment of *Scedosporium* infection and remain in development (Biswas *et al.*, 2018; Rivero-Menendez *et al.*, 2019; Wiederhold *et al.*, 2017).

Paecilomyces

These species are saprophytic hyaline molds distributed globally throughout the world, and a cause of microbiology laboratory contamination. Several species are known to cause human disease, including *Paecilomyces variotti*, *P. marquandii*, *P. javanicus*, *P. fumosoroseus*, *P. viridis*, and *Purpureocillium lilacinum* (formerly *Paecilomyces lilacinus*) (Aguilar *et al.*, 1998). Recently, *P. lilacinum* was reclassified into the newly created genus *Purpureocillium* on the basis of phylogenetic analysis

which places *Paecilomyces* species within the family *Trichomaceae* (*Eurotiales*) and *Purpureocillium lilicanus* within the family *Ophiocordycipitaceae* (*Hypocreales*) (Luangsa-Ard *et al.*, 2011).

Foreign medical devices, including central venous catheters (Chan-Tack *et al.*, 1999; Shing *et al.*, 1996), prosthetic cardiac valves (Allevato *et al.*, 1984; Haldane *et al.*, 1974; Kalish *et al.*, 1982; McClellan *et al.*, 1976), contact lenses and corneal implants (Almeida Oliveira *et al.*, 2019; Chen *et al.*, 2019), and peritoneal dialysis catheters (Uzunoglu and Sahin, 2017), account for the majority of infections caused by *Purpureocillium lilacinum* and *Paecilomyces* species. In immunocompromised individuals, invasive disease appears quite similar to disseminated fusariosis, with manifestation of skin lesions and fungemia (Chamilos and Kontoyiannis, 2005).

As a common contaminant of the microbiology laboratory, diagnosis of clinical disease is made by positive culture in combination with clinical manifestations of infection. *Paecilomyces* species grow rapidly on Sabouraud agar, ranging in color from yellow, pink, brown, or white. Isolates may be confused with *Penicillium* species, based upon similarities of their conidia, however phialides tend to be widely spaced in contrast to *Penicillium* (Sciortino, 2017). Molecular sequencing is available to discriminate to the species level on the basis of the ITS region and beta-tubulin gene (Houbraken *et al.*, 2010). MALDI-TOF-MS identification is promising, but will depend upon improvement of databases before clinical use is reliable (Chen *et al.*, 2015).

The reclassification of *P. lilacinum* into a distinct genus from the *Paecilomyces* helps to explain differences in phenotypic resistance. *P. lilacinum* isolates demonstrate significant resistance to most antifungals, including amphotericin B, fluconazole, itraconazole, flucytosine, and the echinocandins (Castelli *et al.*, 2008; Drogari-Apiranthitou *et al.*, 2012). In contrast, *P. variotii* isolates demonstrate preserved *in vitro* susceptibility to amphotericin B, itraconazole and potentially echinocandins (Castelli *et al.*, 2008; Drogari-Apiranthitou *et al.*, 2012). Both species demonstrate low MIC values for posaconazole, whereas only *P. lilacinum* appears susceptible to voriconazole (Castelli *et al.*, 2008; Drogari-Apiranthitou *et al.*, 2012). No first-line antifungal therapy has been definitively established, but treatment with voriconazole with posaconazole as salvage therapy may be a reasonable option. There are documented cases of successful treatment with voriconazole therapy (Martin *et al.*, 2002; Van Schooneveld *et al.*, 2008), and cases of successful salvage therapy with posaconazole (Almeida Oliveira *et al.*, 2019; Feldman *et al.*, 2016; Kim and Williams, 2014). As with all other hyaline molds, surgical debridement and resolution of underlying immunosuppression improve the chance of cure.

Scopulariopsis

Scopulariopsis is a saprobic, hyaline fungus found ubiquitously in the environment which is rarely pathogenic belonging to the *Microascales* order (Sandoval-Denis *et al.*, 2016). Several species have been documented to cause human infections, with *S. brevicaulis* most commonly implicated. Other less frequently seen pathogenic species include *S. candida*, *S. brumptii* (*Microascus paisii*), and *S. alboflavescens* to name a few (Delliere *et al.*, 2019; Kurata *et al.*, 2018).

Severity of infection caused by *Scopulariopsis* species varies predominantly with host immune status. Onychomycosis, keratitis, and localized infection occur most often in immunocompetent patients, although systemic infection, such as endocarditis has been reported following traumatic inoculation (Migrino *et al.*, 1995). Conversely, immunocompromised persons are at higher risk of invasive or disseminated infection (Helander and Stark, 2017; Neglia *et al.*, 1987), including pneumonia (Kurata *et al.*, 2018), empyema and pericardial effusion (Wuyts *et al.*, 2005), and brain abscess (Patel *et al.*, 1994). Inhalation of *Scopulariopsis* may also result in hypersensitivity pneumonitis in certain hosts (Griable *et al.*, 1975).

Diagnosis is made by isolation of *Scopulariopsis* in culture, or visualization of narrow, branching septate hyphae on histopathology from a clinical specimen. When cultures are positive, colonies grow quickly ranging in color from white to gray. Conidiogenous cells are annellidic, with short, cylindrical stalks with a swollen base. Conidia are globose or ovate and unicellular (Sandoval-Denis *et al.*, 2016).

These species are inherently resistant to most antifungal therapies, making treatment difficult. No optimal therapy has been definitively determined and no guidelines are currently available to aid treatment (Tortorano *et al.*, 2014). *In vitro* susceptibility testing shows high MIC values for amphotericin B, flucytosine, fluconazole, itraconazole, posaconazole and voriconazole (Aguilar *et al.*, 1999; Skora *et al.*, 2015). Echinocandins have no activity against these species (Sandoval-Denis *et al.*, 2013). While terbinafine appears to have fungicidal activity, it has not been effective in clinical treatment of onychomycosis (Steinbach *et al.*, 2004). Susceptibility testing to isavuconazole has not been reported. Combination therapies have been evaluated *in vitro* with triple therapy of posaconazole, terbinafine, and caspofungin (Yao *et al.*, 2015) or amphotericin B, voriconazole, and anidulafungin (Martin-Vicente *et al.*, 2017) showing promise for *S. brevicaulis* isolates. There are a few case reports which announce successful treatment with combination posaconazole and terbinafine in solid organ transplant recipients (Pate *et al.*, 2016; Rakita *et al.*, 2015); however, mortality from invasive *Scopulariopsis* infections remains high. In addition to antifungal therapy, surgical debridement and correction of the underlying immunodeficiency are vital in treating these infections.

Emergomyces

A group of novel dimorphic fungi, *Emergomyces* was first identified in 1994 as the causative agent of a disseminated mycosis in an Italian woman with advanced HIV (Gori *et al.*, 1998). At that time, the species was classified as *Emmonsia* due to morphologic

similarities with the existing genus, as well as genetic analyzes. Thirteen additional cases of disseminated disease were described in South Africa in 2013 among HIV-infected individuals (Kenyon *et al.*, 2013). Further genetic analysis of these cases led to taxonomic revision and five species were identified within the family Ajellomycetaceae: *Emergomyces africanus*, *E. canadensis*, *E. europaeus*, *E. orientalis*, and the type species, *E. pasteurianus* (Dukik *et al.*, 2017). With the exception of *E. pasteurianus* these fungi appear to be geographically restricted in accordance with their species names – that is cases of *E. africanus* have been documented in South Africa and Lesotho (Schwartz *et al.*, 2017), *E. canadensis* in Canada and the United States (Schwartz *et al.*, 2018), *E. europaeus* in Germany (Wellinghausen *et al.*, 2003), and *E. orientalis* in China (Wang *et al.*, 2017). Interestingly, the environment of *Emergomyces* species has not yet been identified, and infection of non-human animals has not been observed (Cronje *et al.*, 2018).

Of the reported cases of *Emergomyces*, a vast majority of patients are suffering from the Acquired Immunodeficiency Syndrome, although a small number of cases in apparently immunocompetent individuals exist. Disseminated emergomycosis appears to be the norm, presenting with cutaneous lesions and pulmonary involvement, which may take a variety of forms (Schwartz *et al.*, 2015).

Cultures are readily positive from skin biopsies, and form tannish colonies which become raised and furrowed with maturation. In their mold form, they are identified by right-angled, branching hyphae with the presence of “florets” – secondary conidiophores with a small, spherical conidia. Definitive species identification may be made by sequencing of the ITS region and β -tubulin genes (Dukik *et al.*, 2017). Importantly, *Emergomyces* species may cross-react with both *B. dermatitidis* DNA probing and *Histoplasma* urine antigen testing (Schwartz *et al.*, 2018; Schwartz *et al.*, 2015).

Very limited data exists regarding the treatment of *Emergomyces* infections. Currently susceptibility data suggest efficacy of amphotericin B, itraconazole, voriconazole, posaconazole, isavuconazole, anidulafungin, and micafungin. These fungi are resistant to fluconazole and flucytosine (Dukik *et al.*, 2018; Maphanga *et al.*, 2017). In general, patients are given induction therapy with amphotericin B, followed by prolonged courses of azole therapy, typically itraconazole, in a fashion similar to treatment for disseminated histoplasmosis. Infection is uniformly fatal without antifungal therapy, although mortality rates still approximate 50% with treatment (Schwartz *et al.*, 2015).

Introduction

Children commonly encounter fungi in the environment, but infrequently develop disease. In healthy children, fungal infections most commonly present as mucocutaneous disease, while invasive fungal infections (IFD) occur primarily in immunocompromised and hospitalized children. In fact, *Candida* spp. are the third most common cause of nosocomial infections in children (Wisplinghoff *et al.*, 2003). Many of the known risk factors for IFD in adults (i.e., hematologic malignancies, ICU admission, and organ transplantation) confer a similar risk of disease in children. There are however important differences in the epidemiology, diagnostic and therapeutic approaches to fungal infections between children and adults, such as unique cohorts that exhibit increased susceptibility to fungal infections. This includes neonates (especially pre-term neonates) and children with primary immunodeficiencies for whom IFD has a very significant impact on morbidity and mortality. Recognition of this fact has led to the successful use of anti-fungal prophylaxis to prevent IFD in these children. Furthermore, the study of fungal disease in children, especially those with defined immune defects, has significantly advanced our understanding of fungal diseases and host response, including the importance of TH17 immunity in preventing mucocutaneous disease. The most common IFD in children are caused by *Candida* and *Aspergillus* spp. and are reviewed in this chapter with a special emphasis on these unique at-risk groups of children.

Candida Infections

Neonates

Invasive candidiasis

Epidemiology

Neonates are disproportionately at risk for invasive candidiasis (IC) with a reported incidence on the order of 11 per 100,000 live births per year (or 15 cases per 10,000 neonatal admissions) (Benedict *et al.*, 2018; Zaoutis *et al.*, 2007). IC is not only more common in neonates but associated with a worse prognosis when compared with the same disease in older children (Hsu *et al.*, 2018). The highest rates of IC occur in premature babies and the risk of IC can be readily stratified based on the extent of prematurity. IC has been reported to occur in 4%–8% of babies weighing less than 1000 g also known as extremely low birth weight infants (ELBW) (reviewed in Kelly *et al.*, 2015). Both the mortality and morbidity of IC are high with death or neurodevelopmental impairment being reported in as many as 73% of ELBW neonates (Benjamin *et al.*, 2006). A variety of medical practices have been identified as risk factors for IC in neonates, including antibiotic exposure (especially 3rd generation cephalosporins), the presence of indwelling catheters, parenteral nutrition, and H2-antagonists. The presence of necrotizing enterocolitis and other GI abnormalities have also been reported as risk factors for invasive candidiasis in neonates (Benjamin *et al.*, 2006). A decrease in the rates of neonatal IC has been linked to the institution of central line care protocols and anti-fungal prophylaxis regimens (reviewed in Benedict *et al.*, 2018). Other fungi like *Aspergillus* and *Malassezia* can occasionally cause disease in neonates, though much less frequently than candida.

Host

Skin and mucosal colonization of the neonate occur quickly after birth as a result of both horizontal and vertical transmission. Candidal colonization often precedes invasive disease and may occur in as many as 23%–60% of neonates, with the higher rates reported in premature neonates (Saiman *et al.*, 2001; Kicklighter *et al.*, 2001). Nonetheless, the minority of colonized neonates go on to develop invasive disease (Baley *et al.*, 1986). Intrauterine transmission of candida infection (via ascending infection or transplacental spread) resulting in congenital disease occurs but is rare despite the relatively common occurrence of candidal vaginitis during pregnancy. In general, the placenta appears to efficiently limit transmission of fungal disease from mothers to neonates as evidenced by low rates of congenital fungal infection (Patel *et al.*, 2012). Neonates with congenital candidiasis usually present within the first day of life with a diffuse, erythematous rash that can be variable in appearance (i.e., macular, vesicular, pustular and desquamating). Blood stream infection with dissemination to other organs may be present at the time of the appearance of the rash or may occur with progression of disease, especially in the absence of prompt therapy (Kaufman *et al.*, 2017).

The specific immune deficiencies that lead to an increased risk of candidiasis in neonates are poorly understood. Animal model experimentation demonstrates that pups are more susceptible to IC when compared to adult animals, supporting the hypothesis that immunologic immaturity of the newborn contributes to an increased susceptibility to candida infection (Trofa *et al.*, 2011). The skin and vernix caseosa of full-term infants, which is lacking or underdeveloped in preterm neonates, produce anti-microbial peptides that have anti-candida activity and may help prevent candida colonization (Marchini *et al.*, 2002). In vitro studies suggest that reduced neutrophil function in neonates (including phagocytosis and oxidative burst) does not play a role as a risk factor for invasive disease in this cohort (Destin *et al.*, 2009), even though neutrophil defects are often a primary risk factor for IC.

Nonetheless, the s-lectin, galectin, which is secreted by neutrophils and is an opsonin for candida is deficient in newborns (Linden *et al.*, 2013). A variety of other immune factors that are developmentally immature in the neonate have been hypothesized to contribute to an increased susceptibility candida infection, including decreased complement components, a decreased number of innate host cells, a decreased and TH2 skewed inflammatory response (reviewed in Michalski *et al.*, 2017).

Pathogen

The most common candida species to cause IC in neonates are *C. albicans* and *C. parapsilosis* (Trofa *et al.*, 2008). Other non-albicans species cause disease in neonates, but much less commonly, including *C. glabrata*, *C. guilliermondii*, *C. tropicalis*, and *C. lusitanae*. The emergence of fluconazole resistance and the appearance of non-albicans strains has been a concern due to the use of fluconazole prophylaxis in NICUS (Brion *et al.*, 2007). However, in a recent review of 137 ELBW infants with IC, fluconazole resistance was only present in isolates from 3% of infants (Autmizguine *et al.*, 2018). Nonetheless, NICU outbreaks of fluconazole resistant, non-albicans candida have been described (Juyal *et al.*, 2013; Khan *et al.*, 2007).

Candida species exhibit a variety of virulence traits, though their role in neonatal disease are unknown. This includes secreted enzymes, which contribute to invasion and host damage, like aspartyl proteases and lipases. In vitro features, including adhesion and cytotoxicity have been reported to correlate with increased virulence of Candida strains isolated from neonates with IC (Bliss *et al.*, 2012). In animal models of neonatal disease lipase deficient mutants of both *C. parapsilosis* and *C. albicans* show decreased virulence relative to wild type strains, highlighting the importance of this enzyme in causing disease (Trofa *et al.*, 2011). An agglutinin protein, which mediates cellular adhesion and invasion, has also been linked with virulence in animal pup experimentation (Liu and Filler, 2011).

The enhanced virulence of *C. albicans* relative to other species of candida may be in part related to its relative unique tendency to form hypha during infection. Biofilm formation also appears to be an important virulence trait for *C. albicans* in the neonatal intensive care unit (NICU) setting. Like most candida, *C. albicans* forms a biofilm that promotes both adhesion to foreign material and decreased susceptibility to anti-fungal therapy. The biofilm of *C. parapsilosis* is biochemically and structurally unique. It appears to confer an enhanced ability to bind to foreign materials, especially in environments with high glucose and lipid concentrations, which is often seen with NICU babies who are receiving parenteral nutrition (reviewed in Chow *et al.*, 2012).

Disease manifestations and outcome

IC in neonates typically presents after the second week of life with sepsis that is indistinguishable from bacterial causes of sepsis. While thrombocytopenia is common, it is not specific for IC and can also be seen with bacterial sepsis. In one study, approximately 26% of ELBW neonates with IC died within 14 days of diagnosis (Benjamin *et al.*, 2006). Persistent candidemia is commonly observed in infected neonates despite anti-fungal therapy (Benjamin *et al.*, 2006). Furthermore, delayed catheter removal is associated with delayed sterilization of the blood and increased mortality (Karlłowicz *et al.*, 2000). Dissemination to multiple organ systems is not infrequent with documented central nervous system (CNS) involvement occurring in approximately 8% of patients (Benjamin *et al.*, 2006). Thus, all neonates with IC should be evaluated for metastatic candida disease. Even in the absence of CNS infection, candida sepsis has been associated with worse developmental outcomes when compared with non-infected neonates (Benjamin *et al.*, 2006; Friedman *et al.*, 2000). Other reported sequelae to occur more commonly in neonates with IC include chronic lung disease, retinopathy of prematurity and peri-ventricular leukomalacia (Friedman *et al.*, 2000).

Mucocutaneous candidiasis

Epidemiology

Oropharyngeal candidiasis (thrush) and candida diaper dermatitis are commonly encountered fungal infections in healthy neonates. Thrush appears as white plaques on the buccal mucosa, tongue or palate of the mouth and can cause discomfort during feeding. Erythema of the tongue, soft palate or buccal mucosa and cracking of the corners of the mouth can also occur. Candida dermatitis typically results from secondary infection of an irritant diaper dermatitis, resulting in a scaly erythematous rash in the diaper area with occasional satellite lesions. While usually self-limited in full-term infants, candidal diaper dermatitis can be a risk factor for the development of systemic candidal infection in premature infants.

Thrush is most commonly seen among babies younger than 1 month of age. It is estimated that approximately 2%–7% of healthy infants develop thrush (Krol and Keels, 2007). In older children, immunocompromising conditions such as HIV and diabetes can also lead to oral candidiasis. Inhaled corticosteroids, frequent or prolonged antibiotic courses, chemotherapy or immunosuppressive medications can also predispose to oral candidiasis. Persistent oral candidiasis or recurrences in children older than 6 months of age should prompt investigation for possible immunodeficiency (Krol and Keels, 2007).

Pathogen and host

C. albicans accounts for approximately 70%–80% of cases of oral candidiasis, with *C. glabrata* and *C. tropicalis* less commonly implicated (Krol and Keels, 2007). Similar to oral candidiasis, 80%–90% of candidal diaper dermatitis is due to *C. albicans*, with *C. tropicalis*, *C. parapsilosis*, and *C. glabrata* found less commonly (Bonifaz *et al.*, 2016). While Candida is a common oral commensal, the presumed age-related factors that promote symptomatic disease in neonates is poorly understood. The pathogenesis of diaper dermatitis is multifactorial with friction from diapers, moisture, exposure to lipases and proteases from feces and urine, and changes in skin microflora, and increases in pH all contributing to maceration of the skin. The resultant impairment of the stratum corneum, promotes invasion by *C. albicans* in the stool (Bonifaz *et al.*, 2016). Premature infants are at particularly high

risk due to a thinner stratum corneum (Sikic Pogacar *et al.*, 2018) and a higher skin pH, that takes longer to normalize (Adam, 2008). A higher skin pH leads to greater activity of fecal enzymes including lipases and proteases which causes increased irritation to the skin (Bonifaz *et al.*, 2016).

Primary Immunodeficiency and Candida Infection

Invasive candidiasis

Primary immunodeficiencies consist of over 300 different disorders that result in impaired immunity. Depending on the underlying immune defect, children with primary immunodeficiencies (PIs) are at an increased risk for developing candida infection that can manifest as IC or chronic mucocutaneous candidiasis (CMC). Disorders of phagocytic function are in particular noted for an increased risk of IC. Children with chronic granulomatous disease (CGD), for example, have defective NADPH oxidase activity resulting in impaired oxygen free radical production by neutrophils. This results in an increased susceptibility to both invasive aspergillus and candida infections. While IC is less common than invasive aspergillosis for CGD patients, it is still an important cause of disease with a reported incidence ranging from 6% to 10% (Antachopoulos *et al.*, 2007; Winkelstein *et al.*, 2000; Henriet *et al.*, 2013). Lymphadenitis, meningitis, and bloodstream infection are the most common forms of disease in children with CGD, while mucocutaneous candidiasis is rarely encountered (Winkelstein *et al.*, 2000). Affected infants typically present with non-specific symptoms of irritability and fever, but may have localizing signs such as lymphadenopathy or hepatosplenomegaly. Myeloperoxidase deficiency, which results in decreased hypochlorous acid production by neutrophils and defective killing of *Candida spp.* in vitro, also confers an increased risk of IC. However, affected patients typically also have other predisposing factors for IC like diabetes (Antachopoulos *et al.*, 2007). Other primary immunodeficiencies resulting in defective neutrophil function have variably be reported to confer an increased risk of IC, including leukocyte adhesion defect and congenital neutropenias (Antachopoulos *et al.*, 2007).

Chronic mucocutaneous candidiasis

Several PIs have been associated with CMC, a condition characterized by chronic skin, nail, oral and genital infections with *Candida spp.* Affected patients develop plaques on the oral, esophageal or genital mucosa and thickened skin and nails. For some PIs, CMC is the primary manifestation of the underlying immune defect, while for others it is a part of a constellation of symptoms. The PIs associated with CMC generally have impaired TH17 immunity, though this may occur as a result of different mechanisms. This observation is consistent with animal experimentation and highlights the importance of IL-17 in the host response to mucosal candida infection (reviewed in Conti and Gaffen, 2015). Job's syndrome, also known as Hyper Immune IgE Syndrome (HIES), is a PI associated with multiple manifestations including CMC, for which the underlying immunodeficiency was only recently recognized. In these patients, mutations in genes that encode the signal transducer and activator of transcription 3 signaling protein (STAT3) result in defective Th17 cell differentiation (Okada *et al.*, 2016). Patients typically have extremely elevated serum IgE levels, decreased Th17 cells, characteristic facial features, eczema, and recurrent pulmonary and staphylococcal skin abscesses. A large cohort study of 60 patients with AD-HIES demonstrated that 85% developed CMC, including oral, esophageal, genital, cutaneous candidiasis as well as chronic onychomycosis (Okada *et al.*, 2016). Other PIs associated with CMC include severe combined immunodeficiency (SCID), STAT1 gain-of-function mutations, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), and mutations in IL-17, IL-12, and IL-23. For some of these conditions (i.e., SCID and IL-12 receptor deficiency), both CMC and IC can occur (reviewed in Okada *et al.*, 2016).

Children with mutations in caspase recruitment domain-containing protein 9 (CARD9) are at risk for both CMC and IC. IC for these patients has a peculiar tendency to involve the central nervous system (CNS) although other organ systems including eyes and bone may also be involved (Corvilain *et al.*, 2018). CARD9 is expressed by neutrophils and monocytes and is part of the signaling pathway that is downstream of dectin-1 and dectin-2, which are C-type lectin receptors that are important for fungal recognition. Affected patients have both impaired neutrophil-mediated killing of *Candida spp.* in vitro and decreased levels of TH17 cells, which may explain their predisposition for both IC and CMC. Besides candida infections, these patients are also at increased risk for other fungal diseases, including non-pulmonary aspergillosis, extensive dermatomycosis, as well as subcutaneous and invasive phaeohyphomycosis.

Diagnosis

Culture

While blood culture is considered the gold standard for the diagnosis of IC, its sensitivity has been reported to vary between 20% and 70% (Clancy and Nguyen, 2013; Avni *et al.*, 2011). In some instances, this is due to the presence of end-organ disease in the absence of fungemia. In patients with fungemia, the number of circulating organisms is often low, making it difficult to isolate the organism. This is especially true in children and premature neonates, for whom the volume of blood that is available for testing is low, in some instances less than 1 ml. Of note, the concentration of circulating yeasts in the blood has been reported to vary based on the infecting species and age of the patient, with higher loads reported for neonates and with disease due to *C. parapsilosis* (Pfeiffer *et al.*, 2011). In immunocompromised children, the detection of *Candida* in the urine can be an indicator of systemic disease and should be investigated accordingly. This is especially true for premature neonates for whom the detection of *Candida* in the urine has been associated with an increased risk of death and impaired neurodevelopmental outcome, similar to that seen in those with candidemia (Wynn *et al.*, 2012).

Fungal antigen and molecular testing

Given the limits of blood culture testing for IC, fungal antigen testing has been developed to enhance the diagnosis of IC. β -D-glucan (BDG) is a polysaccharide constituent of the candida cell wall. This polysaccharide is found in a variety of fungi, but notably not present in Mucormycetes or Cryptococcus. False positives can occur in a variety of clinical settings and complicate the interpretation of results. This includes bacteremia, intravenous immunoglobulin therapy, certain antibiotics (i.e., piperacillin tazobactam, meropenem), and hemodialysis with use cellulose filters (Sulahian *et al.*, 2014; Alexander *et al.*, 2010). Elevated BDG levels have also been reported in children with hematologic malignancies that were colonized with Candida (Wynn *et al.*, 2012). The BDG assay was developed by testing in adults and the appropriate cut-off values for children are not well characterized. Current pediatric data is limited by several factors, including small study size, retrospective nature and differences in methodology (reviewed in Cohen *et al.*, 2020; Lehrnbecher *et al.*, 2016). It is likely that the appropriate pediatric cut-off is not only different from the adult value but likely to vary between different pediatric cohorts. For example, several NICU studies suggest higher cut off values (105–125 pg/ml) are need to discriminate between IC and other serious illness (Goudjil *et al.*, 2013; Cornu *et al.*, 2018). Monitoring of BDG levels in the CSF may be helpful in monitoring response to antifungal therapy (Salvatore *et al.*, 2016). Mannan is another fungal polysaccharide, which has been used diagnostically for IC though minimal pediatric data exists. PCR based assays have been increasingly studied for the diagnosis of IC as they offer rapid turn around and high sensitivity. A PCR combined with a magnetic resonance detection system (T2Candida Panel) has been recently licensed by the FDA for the detection of Candida directly from blood. The assay detects 5 species of Candida, including *C. albicans*, *C. parapsilosis*, *C. tropicalis*, *C. glabrata*, and *C. krusei*. The sensitivity of this assay is reported to be 1 colony-forming unit/ml with a turn-around time of 3–4 h (Mylonakis *et al.*, 2015; Beyda *et al.*, 2013). Preliminary pediatric studies suggest good agreement of this assay with blood culture testing (Hamula *et al.*, 2016).

Aspergillus Infections

Among children with invasive mold infections, *Aspergillus spp.* are responsible for as many as 75% of cases (Wattier *et al.*, 2015). Many of the epidemiologic, clinical and diagnostic features of invasive aspergillosis (IA) in children are similar to those seen in adults, but there are important differences, which are reviewed in this section. *Aspergillus* also causes hypersensitivity lung disease in children with underlying respiratory disease, including cystic fibrosis and asthma. In these instances, colonization of the airway by *Aspergillus species* can result in an exacerbation of underlying respiratory disease (Vicencio *et al.*, 2014).

Invasive Aspergillosis

Epidemiology

Children with hematologic malignancies with or without stem cell transplantation make up the majority of IA cases. Children with primary immunodeficiency and those who have undergone solid-organ transplantation, especially heart and lung recipients are also at risk for IA. IA may also occur in children with lupus and preterm neonates (Silva *et al.*, 2015; Gallais *et al.*, 2017).

Among children with hematologic malignancies, most but not all studies suggest the highest rates of IA in AML patients who typically have more prolonged periods of neutropenia. Likewise, children with recurrent ALL also appear to have an increased risk of IA (Papachristou *et al.*, 2019). Affected children typically have one or more immunologic risk factors for the development of IA including neutropenia, corticosteroid therapy or other immunosuppressive therapy (i.e., calcineurin inhibitors). IA has been reported to cause 4.79% of culture-proven infections in HSCT recipients, though rates tend to vary among sites. Most infections occur in the first 100 days following transplant and often occur in the context of concurrent bacterial, viral or other fungal infections. Graft versus host disease and the immunosuppression used to treat this entity are a recognized risk factor for IA. When compared to HSCT, children undergoing solid-organ transplantation are significantly lower risk of IA with reported rates typically less than 1% (Zaoutis *et al.*, 2006). The exception to this is lung transplantation (especially in patients with cystic fibrosis) where aspergillosis may occur in as many as 5% of patients (Zaoutis *et al.*, 2006).

Among the primary immunodeficiencies (PIs), chronic granulomatous disease (CGD) is most closely linked to enhanced susceptibility to aspergillus infection. CGD occurs in 1/200,000 births and results from an impaired ability to generate an oxidative burst with a resulting decrease in superoxide free radical production secondary to defects in nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. IA is one of the most common causes of serious infections in children with CGD, affecting approximately 40% of patients (Marciano *et al.*, 2015; Blumental *et al.*, 2011). Differences in the incidence of IA among CGD patients appears to be attributable to differences in residual NADPH activity, and associated oxidative burst activity. The X-linked form of disease accounts for approximately 80% of all CGD. X-linked CGD is the most severe form of CGD and is associated with earlier presentation (most by age 2) and earlier onset of IA (Bortoletto *et al.*, 2015).

IA may also occur in other primary immunodeficiencies that result in either quantitative or qualitative defects in neutrophil function (i.e., leukocyte adhesion defect, congenital neutropenias, Wiskott–Aldrich Syndrome). In children with CARD9 deficiency, which is associated with chronic mucocutaneous candidiasis, defects in neutrophil migration may result in extra-pulmonary aspergillosis (Rieber *et al.*, 2016). T cell defects can also be associated with an increased risk of IA. In children with Job's syndrome

(also known as Hyper-IgE syndrome), aspergillus is known to superinfect pneumatoceles and invade blood vessels. Approximately 20% of patients with Hyper-IgE syndrome develop IA and 17% of these infections lead to death (Chandesris *et al.*, 2012). IA may also occur in newborns, though it is significantly much less common than invasive candidiasis. Primary cutaneous aspergillosis with and without secondary dissemination is well described in premature newborns, typically in association with nosocomial contamination of areas of the skin that are damaged (Woodruff and Hebert, 2002).

Organism

Similar to IA in adults, *A. fumigatus* is the most common species isolated from children with IA, with the most commonly involved site being the lungs (Burgos *et al.*, 2008). Other *Aspergillus* species that have been implicated in pediatric IA include *A. flavus*, *A. terreus*, *A. niger*, and *A. nidulans*. A unique characteristic of IA in CGD is the high frequency of *A. nidulans* infections, ranging from 38% to 47% of cases (reviewed in King *et al.*, 2016). The basis of increased frequency of *A. nidulans* in CGD patients is poorly understood and may not be related to ROS deficiency (Henriet *et al.*, 2012). There has been increasing recognition of infections due to less common species of *Aspergillus* in patients with primary immunodeficiencies. This includes the organisms, *A. pseudoviridinutans*, *A. tanneri*, *A. udagawae*, which may have unusual anti-fungal susceptibility patterns (reviewed in Seyedmousavi *et al.*, 2018).

Pathogenesis

While a complete review of the pathogenesis of IA is beyond the scope of this chapter the study of IA in children with CGD has led to a better understanding of the role of NADPH in the host response to infections and will be reviewed here. IA begins with the inhalation of conidia, which are able to bind to respiratory epithelium. Conidia that avoid macrophage killing germinate to form hyphae, which are targeted by infiltrating neutrophils. The host response to the conidial and hyphal forms are distinct, though both rely to varying degrees upon the generation of oxygen free radicals to limit organism growth. The NADPH defects associated with CGD appear to result in increased susceptibility to *Aspergillus* infections as a result of several different mechanisms including impaired intracellular killing activity of neutrophils and possibly by macrophages. Decreased ROS production also hinders the release of preformed proteases by neutrophils and the development of neutrophil extracellular traps (NETs). NETs consist of extracellular collections of neutrophil-derived chromatin and granules, which are essential in limiting the growth of the hyphae, which are too large to undergo phagocytosis. Gene therapy which allowed for the restoration of NET formations has been reported to result in a cure of refractory IA in a child with CGD (Bianchi *et al.*, 2009).

Decreased ROS levels have also been hypothesized to contribute to the exuberant inflammation, which is typical in children with CGD and IA. Histopathologic exam of affected tissues typically reveals extensive granuloma formation with infiltrating neutrophils containing fungal elements. Of note, angioinvasion by hyphal elements which is characteristic of IA in non-CGD patients is absent, suggesting that ROS is not necessary to prevent this aspect of disease. Several different anti-inflammatory mechanisms of ROS have been proposed including increased proinflammatory cytokine and chemokine production as well as impaired neutrophil apoptosis (reviewed in Segal *et al.*, 2012). In mice, decreased ROS production interferes with tryptophan metabolism which results in enhanced inflammation through augmented IL-17 activity, though the role of this process in children with CGD is unclear (Romani *et al.*, 2008).

Clinical

In children with IA, in association with an underlying malignancy, the lungs are the most common site of involvement though other organ systems, including the sinuses, bone, skin, and brain, can be involved by both direct and hematogenous extension of infection. More than one organ system is involved in as many as 35% of cases (Abbasi *et al.*, 1999). The presentation of IA depends on the underlying risk factor and the organ system involved. In children with hematologic malignancies, a diagnosis of IA is commonly first considered as a result of abnormal radiographic studies of the chest or sinuses, which were done for the evaluation of fever in the context of neutropenia (Abbasi *et al.*, 1999). However, patients may also present with symptoms indicative of the site of disease, including but not limited to skin lesions, facial swelling or increased nasal drainage, respiratory symptoms, and headache (Abbasi *et al.*, 1999). Despite therapy, the mortality of IA in this cohort is high, with rates ranging from 22% to 52.5%, with the highest mortality reported in stem cell recipients (Zaoutis *et al.*, 2006; Burgos *et al.*, 2008). Other reported risk factors for death include GVHD, steroid therapy, immunosuppression, and surgery following diagnosis (Burgos *et al.*, 2008).

In children with CGD, the lungs are also the primary site of disease in the majority of cases. Extension of infection into the bones, mostly in the adjacent thoracic cavity, has been reported to occur in 41%–74% of cases (Henriet *et al.*, 2013). Dissemination to the brain can also occur though this is much less common. Symptoms of IA may be absent in 1/3 of the cases or non-specific such as generalized malaise and failure to thrive. In a French study of CGD patients admitted with invasive mold infections, respiratory symptoms and fever were present in 55% and 38% of patients respectively (Blumental *et al.*, 2011). IA in children with CGD may also present as a chronic progressive infection and occasionally as an acute, severe pneumonitis due to exposure to a high inoculum of conidia (aka mulch pneumonitis) (Henriet *et al.*, 2013). Overall, signs and symptoms of IA tend to be more subtle in children with CGD compared to children with underlying hematologic malignancies. This is especially true for *A. nidulans* disease, even though this infection is particularly aggressive and more likely to be associated with local extension into the thoracic bones and death (Henriet *et al.*, 2012; Dotis and Roilides, 2004).

Diagnosis

Radiologic features

Plain X rays and CT scans are useful in the diagnosis of pulmonary IA in children. However, the most common radiologic features are non-specific and include: segmental and multi-lobar consolidation, perihilar infiltrates, multiple small nodules, peripheral nodular masses, and pleural effusions (Thomas *et al.*, 2003; Taccone *et al.*, 1993; Katragkou *et al.*, 2017). Air crescent and halo signs, which are commonly seen in adult cases of IA appear to be less commonly observed in children (Burgos *et al.*, 2008; Taccone *et al.*, 1993). This is especially true for children with CGD, for whom angio-invasion is not present. It is important to note that the progression of radiologic findings does not necessarily correlate with clinical response (reviewed in Steinbach, 2010).

Culture

Blood cultures in children with IA are typically negative and culture of affected tissue is considered the gold standard of IA diagnosis. Isolation of the organism in culture allows for speciation and susceptibility testing. This is particularly important for children with CGD and other PIs who receive chronic anti-fungal prophylaxis and who are at increased risk for infections due to non-fumigatus species with reduced anti-fungal drug susceptibility (Seyedmousavi *et al.*, 2018). For children with hematologic malignancy and HSCT, some but not all studies indicate a higher yield for an infectious diagnosis with lung biopsy compared to BAL, though this procedure is associated with higher complication rates (Qualter *et al.*, 2014; Chellapandian *et al.*, 2015). Lung biopsy has been reported to have a higher yield over BAL for the diagnosis of IA in CGD (including adults) (King *et al.*, 2016; Salvator *et al.*, 2015).

Fungal antigen and molecular studies

Due to the low incidence of fungemia and positive blood cultures in patients with IA, additional tools have been developed to assist in the diagnosis of this disease. Some of these assays are based upon the detection of fungal/Aspergillus polysaccharides, including galactomannan (GM) and β -D-glucan (BDG) in the serum or other biologic fluids. GM testing is more specific for IA than BDG testing, as BDG can be found in a large number of fungi, including *Candida spp.* and *Pneumocystis*. Both tests are commonly employed as screening tools in children with fever and neutropenia and in diagnostic scenarios, (i.e., in patients with suspected disease). These tests were originally developed based on adult studies and appear to have overall less diagnostic utility in children for unclear reasons. A relatively recent metaanalysis highlights the high degree of variability testing results in pediatric studies (Lehrnbecher *et al.*, 2016). GM testing was found to have an overall sensitivity of 68% and 89% when used for screening and diagnosis, respectively. The positive and negative predictive values ranged from 0% to 100% and 70%–100%, respectively. Less data exists for the role of GM testing in bronchoalveolar fluid (BAL) of pediatric patients. Reported sensitivity and positive predictive values range from 72% to 82% and 58%–82%, respectively (Desai *et al.*, 2009; de Mol *et al.*, 2013). Aspergillus PCR assays have also been developed, though again pediatric data is lacking. In adults, PCR testing of blood appears to have limited utility, while testing of BAL and affected tissue has increased sensitivity (reviewed in Lehrnbecher *et al.*, 2018). PCR technology also offers the potential for both the identification of species and anti-microbial resistance, though additional refinements in the current assay are necessary. It is important to note that, the utility of serum fungal antigen and PCR testing is even more limited in children with CGD. The basis for false-negative results in this cohort is unclear but could be related to differences in pathogenesis (i.e., lack of angioinvasion in CGD patients) and the use of chronic anti-aspergillus prophylaxis.

Antifungal Treatment in Children With IFD

Anti-fungal prophylaxis is routinely used for children with a variety of conditions who are at high risk for IFD, including prematurity, CGD, AML, aplastic anemia, HSCT and solid-organ transplantation. For neonates, the decision to institute anti-fungal prophylaxis should be based on the local incidence of IFD along with the presence of risk factors, i.e., prematurity and antibiotic usage (Pappas *et al.*, 2016). Fluconazole is the most commonly used agent for prophylaxis in the NICU. There have been multiple studies documenting the safety and efficacy of fluconazole prophylaxis in preventing IC in preterm neonates (Clemenson *et al.*, 2015). For children with CGD, universal anti-fungal prophylaxis with an aspergillus active agent is the standard of care (Thomsen *et al.*, 2016). Itraconazole is generally used for this purpose and has been reported to decrease the incidence of IFD by 50% or more (Beaute *et al.*, 2011; Gallin *et al.*, 2003). Itraconazole, however, is poorly absorbed following oral administration, and absorption with the liquid formulation is superior to that observed with capsules. Dosing for younger children (i.e., less than 13 years) is done on a mg per kg basis, though currently recommended doses have recently been reported to result in subtherapeutic levels (Leong *et al.*, 2019). In all children receiving anti-fungal prophylaxis, the potential for breakthrough infection with resistant fungi is always a concern, and this has been described for both neonates and children with CGD (Sarvikivi *et al.*, 2005; Warris *et al.*, 2002).

Specific treatment recommendations for invasive fungal infections are beyond the scope of this chapter, but pediatric guidelines are available elsewhere (Pappas *et al.*, 2016; Ullmann *et al.*, 2018; Patterson *et al.*, 2016). In the absence of primary pediatric data, many treatment recommendations are based on findings from adult studies combined with PK data from pediatric studies, which may be small in size. In some instances, anti-fungal therapy in children is further limited by the lack of even PK data. For example, there is no current pediatric data isavuconazole dosing, though pediatric studies are underway.

There are currently four classes of antifungals (azoles, echinocandins, polyenes and pyrimidine analogs) that are used for the treatment of IFD in adults and children. For all four classes, there are important pediatric dosing considerations. Doses in children

are typically based on a mg/kg and have to take into account age-related differences in pharmacokinetics and pharmacodynamics. For example, the serum half-life and terminal elimination phase of amphotericin-B, a polyene antifungal, are both longer in neonates than in older children (Baley *et al.*, 1990). It also has better cerebrospinal fluid (CSF) penetration among pre-term neonates when compared to adults (Stockmann *et al.*, 2014). Furthermore, rates of nephrotoxicity associated with amphotericin-b deoxycholate are considerably less in infants and children when compared to adults. Current treatment guidelines, accordingly, still include amphotericin-B deoxycholate as first-line therapy for invasive candidiasis in neonates with lipid preparations of amphotericin, fluconazole and echinocandins listed as alternatives (Pappas *et al.*, 2016). In contrast, amphotericin B deoxycholate is now infrequently used in adults for treatment of IC because of concerns of renal toxicity. It should be noted that the recommendation for amphotericin-b deoxycholate for neonatal IC is based primarily on reported experience as opposed to comparison trials with other anti-fungal agents, for which there is little data (Driessen *et al.*, 1996). In a recent phase III study, which compared micafungin versus amphotericin B deoxycholate for the treatment of IC in the neonate, 30 subjects were enrolled. No differences in fungal free survival and tolerability between the two agents were noted (Benjamin *et al.*, 2018). The choice of which anti-fungal to use for the empiric treatment of IC in the NICU should take into account several variables, including organ system involvement, local resistance patterns, prior exposure to anti-fungal therapies (i.e., prophylaxis) and presence of renal insufficiency.

Voriconazole is another anti-fungal agent for which age-related differences in pharmacokinetic properties have important dosing and therapeutic implications for use in children with IFD. Due to its improved efficacy and decreased toxicity, voriconazole has replaced amphotericin as the primary drug of choice for the treatment of IA. However, attaining therapeutic levels can be problematic in younger children (i.e., <12 years of age), presumably due to a combination of factors including dose-related variability in kinetics and impaired oral absorption (Walsh *et al.*, 2004; Karlsson *et al.*, 2009). Racial differences in CYP2C19 alleles, which code for the main enzyme responsible for voriconazole metabolism, also contribute significantly to variation in voriconazole levels in children.

Contents of Volume 2	v
List of Contributors for Volume 2	ix
Contents of All Volumes	xv

VOLUME 2

Exposure to Fungi in Health Care Facilities <i>Raquel Sabino</i>	1
Elderly Exposure to Fungi: A Review Study <i>Marina Almeida-Silva and Cristiana Pereira</i>	11
Integrating Fungi in the Drinking Water Regulation and in Guidelines for Materials in Contact With Drinking Water. Is there Room for Change? <i>Monika Novak Babič, João Brandão, and Nina Gunde-Cimerman</i>	16
Mycological Studies in Cultural Heritage <i>Ana C Pinheiro and Sílvia Sequeira</i>	27
How to Assess Fungal Contamination in School Environments <i>Beatriz de Almeida and Carla Viegas</i>	40
Airborne Fungi in Workplace Atmospheres: Overview of Active Sampling and Offline Analysis Methods Used in 2009–2019 <i>Xavier Simon and Pauline Loison</i>	49
Fungal Contamination of Sawmills <i>Anne Straumfors and Anani Afanou</i>	59
Next-Generation Sequencing in Environmental Mycology. A Useful Tool? <i>Hamza Mbareche</i>	73
Fungal Contamination of Swimming Pools and Fitness Centers <i>Beatriz Almeida and Carla Viegas</i>	84
Occupational Fungal Exposure and Assessment on Animal Production <i>Marta Dias, Pedro Sousa, and Carla Viegas</i>	91
Fungal Prevalence on Waste Industry – Literature Review <i>Marta Dias and Carla Viegas</i>	99
<i>Aspergillus</i> in Indoor Environments <i>Malcolm D Richardson and Riina Rautemaa-Richardson</i>	107
Fungal Exposure in Agricultural Environments – A Review <i>Pedro Sousa and Carla Viegas</i>	116
Fungal Contamination of Beaches <i>Esther Segal and Daniel Elad</i>	125
Fungal Exposure and Relevant Recreational Settings <i>João Brandão, Chelsea Weiskerger, and Monika Novak Babič</i>	130

Assessment of <i>Aspergillus</i> Section <i>Fumigati</i> in Occupational Environments – A Bibliographic Review <i>Pedro Sousa and Carla Viegas</i>	139
Screening of Fungal Azole Resistance in Different Environmental Samples <i>Pedro Pena, Joana Morais, Liliana A Caetano, and Carla Viegas</i>	150
Assessment of Azole Resistance in Healthcare Facilities <i>Liliana Aranha Caetano, Natália Costa, and Cátia Oliveira</i>	159
Climate Change and Aflatoxins Contamination in the Iberian Peninsula <i>Ricardo Assunção, Ariane Vettorazzi, Elena González-Peñas, and Carla Martins</i>	168
The Usefulness of Human Biomonitoring in the Case of Mycotoxins Exposure Assessment <i>Susana Viegas and Carla Martins</i>	176
Mycotoxins as Endocrine Disruptors – An Emerging Threat <i>Carla Martins, Arnau Vidal, Marthe De Boevre, and Ricardo Assunção</i>	180
Fungi in Milk and in Dairy Products <i>Karolina Ropejko, Jan Grajewski, and Magdalena Twarużek</i>	193
Profile of Fungi in Dietary Supplement, Based on Plant Raw Material <i>Iwona Altyn and Magdalena Twarużek</i>	201
Molds in Food Spoilage <i>Magdalena Twarużek, Ewelina Soszczyńska, and Justyna Kwiatkowska-Giżyńska</i>	208
Mycobiota Causing Diseases in Pets <i>Elena Piecková</i>	215
Production of Native and Recombinant Enzymes by Fungi for Industrial Applications <i>Jean-Paul Ouedraogo and Adrian Tsang</i>	222
Fungal Laccases as Biocatalysts for Wide Range Applications <i>Felipe de Salas and Susana Camarero</i>	233
Fungal Lignin-Modifying Peroxidases and H ₂ O ₂ -Producing Enzymes <i>Miia R Mäkelä, Kristiina S Hildén, and Jaana Kuuskeri</i>	247
Fungal Peroxygenases – A Versatile Tool for Biocatalysis <i>René Ullrich, Alexander Karich, and Martin Hofrichter</i>	260
Fungal Lytic Polysaccharide Monooxygenases (LPMOs): Biological Importance and Applications <i>Anikó Várnai, Olav A Hegnar, Svein J Horn, Vincent GH Eijssink, and Jean-Guy Berrin</i>	281
Applications of Fungal Cellulases <i>Astrid Müller, Joanna E Kowalczyk, and Miia R Mäkelä</i>	295
Applications of Fungal Hemicellulases <i>Uttam Kumar Jana and Naveen Kango</i>	305
Applications of Fungal Pectinases <i>María G Zavala-Páramo, Maria G Villa-Rivera, Alicia Lara-Márquez, Everardo López-Romero, and Horacio Cano-Camacho</i>	316
Fungal Biotechnology: Fungal Amylases and Their Applications <i>Rosemary A Cripwell, Willem Heber van Zyl, and Marinda Viljoen-Bloom</i>	326
Applications of Fungal Inulinases <i>Ritumbhara Choukade and Naveen Kango</i>	337
Fungal Proteases: Current and Potential Industrial Applications <i>Aleksandrina Patyshakuliyeva</i>	348
Multifarious Applications of Fungal Phytases <i>Parvinder Kaur, Ashima Vohra, and Tulasi Satyanarayana</i>	358

Modification of Plant Carbohydrates Using Fungal Enzymes <i>Mirjam A Kabel, Matthias Frommhagen, Peicheng Sun, and Henk A Schols</i>	370
Production of Oligosaccharides by Fungi or Fungal Enzymes <i>Maíra N de Almeida and Gabriela P Maitan-Alfenas</i>	385
Metabolic Modeling of Fungi <i>Sebastián N Mendoza, Sara Calhoun, Bas Teusink, and María Victoria Aguilar-Pontes</i>	394
Production of Organic Acids by Fungi <i>Levente Karaffa and Christian P Kubicek</i>	406
Biotechnological Advancements, Innovations and Challenges for Sustainable Xylitol Production by Yeast <i>Sara L Baptista, Aloia Romani, and Lucília Domingues</i>	420
Biotechnology of Wine Yeasts <i>Niël van Wyk, Christian von Wallbrunn, Jan H Swiegers, and Isak S Pretorius</i>	428
Ethanol Tolerance and Production by Yeasts <i>Sandra Garrigues and Sonia Salazar-Cerezo</i>	447
The Biosynthesis of Fungal Secondary Metabolites: From Fundamentals to Biotechnological Applications <i>Olga Mosunova, Jorge C Navarro-Muñoz, and Jérôme Collemare</i>	458
Degradation of Homocyclic Aromatic Compounds by Fungi <i>Ronnie JM Lubbers and Ronald P de Vries</i>	477
Genetic Engineering for Strain Improvement in Filamentous Fungi <i>Sandra Garrigues, Natalia Martínez-Reyes, and Ronald P de Vries</i>	489
Strain Improvement and Genetic Engineering of <i>Trichoderma</i> for Industrial Applications <i>Peijie Chen, Guan Pang, Feng Cai, and Irina S Druzhinina</i>	505
Expression of Recombinant Fungal Proteins in <i>Pichia Pastoris</i> <i>Naoki Sunagawa and Kiyohiko Igarashi</i>	518
Transcriptional Regulation: How Saprobic Fungi Tune the Production of Plant Cell Wall Degrading Enzymes <i>Joanna E Kowalczyk and Paul Daly</i>	528
Bioinformatics Approaches for Fungal Biotechnology <i>Jiajia Li, Ronald P de Vries, and Mao Peng</i>	536
Production of Biofuels From Biomass by Fungi <i>Eva Ottum, Scott E Baker, and Erin L Bredeweg</i>	555
Oleaginous Fungi in Biorefineries <i>Shousong Zhu, Gregory Bonito, Yinhua Chen, and Zhi-Yan Du</i>	577
Role of Fungi in Fermented Foods <i>Garima Maheshwari, Jenny Ahlborn, and Martin Rühl</i>	590
The Application of Fungal Biomass as Feed <i>Sajjad Karimi, Jorge A Ferreira, and Mohammad J Taherzadeh</i>	601
Applications of Fungal Polysaccharides <i>Monika Osińska-Jaroszuk, Justyna Sulej, Magdalena Jaszek, and Jolanta Jaroszuk-Ścisł</i>	613
Development of Mycoherbicides <i>Alexander Berestetskiy</i>	629
Biofungicides: An Eco-Friendly Approach for Plant Disease Management <i>Ana C dos Santos Gomes, Ronivaldo R da Silva, Silvino I Moreira, Samara NC Vicentini, and Paulo C Ceresini</i>	641

Degradation of Plastics by Fungi <i>Wolfgang Zimmermann</i>	650
Treatment of Industrial Wastewaters and Liquid Waste by Fungi <i>Karina Michalska, Anna Goszkiewicz, Kinga Skalska, Eliza Kołodziejczyk, Justyna Markiewicz, Rafał Majzer, and Marcin Siedlecki</i>	662
Antitumor and Immunomodulatory Compounds from Fungi <i>Rosario Nicoletti</i>	683
Mycelium Materials <i>Freek VW Appels and Han AB Wösten</i>	710
Subject Index	719

LIST OF CONTRIBUTORS FOR VOLUME 2

Iwona Ałtyn
Kazimierz Wielki University, Bydgoszcz, Poland

Anani Afanou
National Institute of Occupational Health, Oslo, Norway

María Victoria Aguilar-Pontes
*Utrecht University, Utrecht, The Netherlands and
Concordia University, Montreal, QC, Canada*

Jenny Ahlborn
University of Giessen, Giessen, Germany

Beatriz de Almeida
*Polytechnic Institute of Lisbon, Lisbon, Portugal and
Health & Technology Research Center, Lisbon School of
Health Technology, Polytechnic Institute of Lisbon,
Lisbon, Portugal*

Maíra N. Almeida
*Federal University of São João del-Rei, São João del Rei,
Brazil*

Marina Almeida-Silva
*Centro de Ciências e Tecnologias Nucleares, Instituto
Superior Técnico, Universidade de Lisboa, E.N. 10 ao
km 139, 7, 2695-066 Bobadela LRS, Portugal and
H&TRC-Health & Technology Research Center,
ESTeSL-Escola Superior de Tecnologia da Saúde,
Instituto Politécnico de Lisboa*

Freek V.W. Appels
Utrecht University, Utrecht, The Netherlands

Ricardo Assunção
*National Institute of Health Dr. Ricardo Jorge, Lisbon,
Portugal; Centre for Environmental and Marine Studies,
University of Aveiro, Aveiro, Portugal; and NOVA
University Lisbon, Lisbon, Portugal*

Monika Novak Babič
University of Ljubljana, Ljubljana, Slovenia

Scott E. Baker
*Pacific Northwest National Laboratory, Richland, WA,
United States and Joint BioEnergy Institute, US
Department of Energy, Emeryville, CA, United States*

Sara L. Baptista
*Centre of Biological Engineering, University of Minho,
Braga, Portugal*

Alexander Berestetskiy
*All-Russian Institute of Plant Protection,
Saint-Petersburg, Russian Federation*

Jean-Guy Berrin
Aix-Marseille University, Marseille, France

Gregory Bonito
*Michigan State University, East Lansing, MI,
United States*

João Brandão
*National Institute of Health Doutor Ricardo Jorge,
Lisboa, Portugal and University of Lisboa, Lisboa,
Portugal*

Erin L. Bredeweg
*Pacific Northwest National Laboratory, Richland, WA,
United States*

Liliana A. Caetano
*Health & Technology Research Center, Lisbon School of
Health Technology, Polytechnic Institute of Lisbon,
Lisbon, Portugal; University of Lisbon, Lisbon, Portugal;
and Polytechnic Institute of Lisbon, Lisbon, Portugal and
University of Lisbon, Lisbon, Portugal*

Feng Cai
*Nanjing Agricultural University, Nanjing, China and
Vienna University of Technology, Vienna, Austria*

Sara Calhoun
*DOE Joint Genome Institute, Walnut Creek, CA,
United States*

Susana Camarero
Spanish National Research Council, Madrid, Spain

Horacio Cano-Camacho
*Multidisciplinary Center for Studies in Biotechnology,
Faculty of Veterinary Medicine and Zootechnics,
Michoacan University of Saint Nicholas of Hidalgo,
Morelia, Michoacán, México*

Paulo C. Ceresini
Sao Paulo State University, Sao Paulo, Brazil

Peijie Chen
Nanjing Agricultural University, Nanjing, China

Yinhua Chen
Hainan University, Haikou, China

Ritumbhara Choukade
*Department of Microbiology, Dr. Harisingh Gour
Vishwavidyalaya (A Central University), Sagar, Madhya
Pradesh, India*

Jérôme Collemare
*Westerdijk Fungal Biodiversity Institute, Utrecht,
The Netherlands*

Natália Costa
Lisbon School of Health Technology, Lisbon, Portugal

Rosemary A. Cripwell
Stellenbosch University, Stellenbosch, South Africa

Ronivaldo R. da Silva
Sao Paulo State University, Sao Paulo, Brazil

Paul Daly
*Utrecht University, Utrecht, The Netherlands and
Institute of Plant Protection, Jiangsu Academy of
Agricultural Sciences, Nanjing, People's Republic of
China*

Marthe De Boevre
Ghent University, Ghent, Belgium

Cátia Oliveira
Lisbon School of Health Technology, Lisbon, Portugal

Felipe de Salas
Spanish National Research Council, Madrid, Spain

Ronald P. de Vries
*Fungal Physiology, Westerdijk Fungal Biodiversity
Institute & Fungal Molecular Physiology, Utrecht
University, Utrecht, The Netherlands*

Marta Dias
*Health & Technology Research Center, Lisbon School of
Health Technology, Polytechnic Institute of Lisbon,
Lisbon, Portugal*

Lucília Domingues
*Centre of Biological Engineering, University of Minho,
Braga, Portugal*

Ana C. dos Santos Gomes
Sao Paulo State University, Sao Paulo, Brazil

Irina S. Druzhinina
*Nanjing Agricultural University, Nanjing, China and
Vienna University of Technology, Vienna, Austria*

Zhi-Yan Du
*Michigan State University, East Lansing, MI,
United States*

Vincent G.H. Eijsink
Norwegian University of Life Sciences, Ås, Norway

Daniel Elad
The Kimron Veterinary Institute, Rishon Le Zion, Israel

Jorge A. Ferreira
University of Borås, Borås, Sweden

Matthias Frommhagen
*Wageningen University and Research, Wageningen,
The Netherlands*

Sandra Garrigues
*Fungal Physiology, Westerdijk Fungal Biodiversity
Institute & Fungal Molecular Physiology, Utrecht
University, Utrecht, The Netherlands*

Elena González-Peñas
University of Navarra, Pamplona, Spain

Anna Goszkiewicz
*Research and Innovation Centre Pro-Akademia,
Konstantynów Łódzki, Poland*

Jan Grajewski
Kazimierz Wielki University, Bydgoszcz, Poland

Nina Gunde-Cimerman
University of Ljubljana, Ljubljana, Slovenia

Olav A. Hegnar
Norwegian University of Life Sciences, Ås, Norway

Kristiina S. Hildén
University of Helsinki, Helsinki, Finland

Martin Hofrichter
*TU Dresden, International Institute Zittau, Zittau,
Germany*

Svein J. Horn
Norwegian University of Life Sciences, Ås, Norway

Kiyohiko Igarashi
*The University of Tokyo, Tokyo, Japan and VTT
Technical Research Centre of Finland, Espoo, Finland*

Uttam Kumar Jana
*Dr. Harisingh Gour Vishwavidyalaya (A Central
University), Sagar, Madhya Pradesh, India*

Jolanta Jaroszuk-Ścisiel
Maria Curie-Skłodowska University, Lublin, Poland

Magdalena Jaszek
Maria Curie-Skłodowska University, Lublin, Poland

Mirjam A. Kabel
*Wageningen University and Research, Wageningen,
The Netherlands*

Naveen Kango
*Department of Microbiology, Dr. Harisingh Gour
Vishwavidyalaya (A Central University), Sagar, Madhya
Pradesh, India*

Levente Karaffa
*Department of Biochemical Engineering, Faculty of
Science and Technology, University of Debrecen,
Debrecen, Hungary*

Alexander Karich
TU Dresden, International Institute Zittau, Zittau,
Germany

Sajjad Karimi
University of Borås, Borås, Sweden

Parvinder Kaur
Swami Shraddhanand College (University of Delhi),
Delhi, India

Eliza Kołodziejczyk
Research and Innovation Centre Pro-Akademia,
Konstantynów Łódzki, Poland

Joanna E. Kowalczyk
University of Helsinki, Helsinki, Finland

Christian P. Kubicek
Institute of Chemical, Environmental and Bioscience
Engineering, TU Wien, Vienna, Austria

Jaana Kuuskeri
University of Turku, Turku, Finland

Justyna Kwiatkowska-Giżyńska
Kazimierz Wielki University, Bydgoszcz, Poland

Alicia Lara-Márquez
Multidisciplinary Center for Studies in Biotechnology,
Faculty of Veterinary Medicine and Zootechnics,
Michoacan University of Saint Nicholas of Hidalgo,
Morelia, Michoacán, México

Jiajia Li
Utrecht University, Utrecht, The Netherlands

Pauline Loison
French Research and Safety Institute for the Prevention
of Occupational Accidents and Diseases, Vandoeuvre les
Nancy, France

Ronnie J.M. Lubbers
Westerdijk Fungal Biodiversity Institute, Utrecht,
The Netherlands

Everardo López-Romero
Department of Biology, University of Guanajuato,
Guanajuato, México

Garima Maheshwari
University of Giessen, Giessen, Germany

Gabriela P. Maitan-Alfenas
Federal University of Viçosa, Viçosa, Brazil

Rafał Majzer
Research and Innovation Centre Pro-Akademia,
Konstantynów Łódzki, Poland

Justyna Markiewicz
Research and Innovation Centre Pro-Akademia,
Konstantynów Łódzki, Poland

Carla Martins
Food and Nutrition Department, National Institute of
Health Doutor d Ricardo Jorge, Lisboa, Portugal;
CESAM, Centre for Environmental and Marine Studies,
University of Aveiro, Campus Universitário de Santiago,
Aveiro, Portugal; NOVA National School of Public
Health, Universidade NOVA de Lisboa, Lisboa,
Portugal; and CISP, Centro de Investigação em Saúde
Pública, Universidade NOVA de Lisboa, Lisboa, Portugal

Natalia Martínez-Reyes
Fungal Physiology, Westerdijk Fungal Biodiversity
Institute & Fungal Molecular Physiology, Utrecht
University, Utrecht, The Netherlands

Hamza Mbareche
Sunnybrook Research Institute, Toronto, ON, Canada
and University of Toronto, Toronto, ON, Canada

Sebastián N. Mendoza
Vrije Universiteit Amsterdam, Amsterdam, The
Netherlands

Karina Michalska
Research and Innovation Centre Pro-Akademia,
Konstantynów Łódzki, Poland

Joana Morais
Health & Technology Research Center, Lisbon School of
Health Technology, Polytechnic Institute of Lisbon,
Lisbon, Portugal

Silvino I. Moreira
Sao Paulo State University, Sao Paulo, Brazil

Olga Mosunova
Westerdijk Fungal Biodiversity Institute, Utrecht,
The Netherlands

Miia R. Mäkelä
University of Helsinki, Helsinki, Finland

Astrid Müller
Fungal Physiology, Westerdijk Fungal Biodiversity
Institute & Fungal Molecular Physiology, Utrecht
University, Utrecht, The Netherlands

Jorge C Navarro-Muñoz
Westerdijk Fungal Biodiversity Institute, Utrecht,
The Netherlands

Rosario Nicoletti
Council for Agricultural Research and Economics,
Research Center for Olive, Fruit and Citrus Crops,
Caserta and Department of Agriculture, University of
Naples Federico II, Portici, Italy

Monika Novak Babič
University of Ljubljana, Ljubljana, Slovenia

Monika Osińska-Jaroszuk
Maria Curie-Skłodowska University, Lublin, Poland

Eva Ottum
*Pacific Northwest National Laboratory, Richland, WA,
United States and Boston College, Boston, MA,
United States*

Jean-Paul Ouedraogo
Concordia University, Montreal, QC, Canada

Guan Pang
Nanjing Agricultural University, Nanjing, China

Aleksandrina Patyshakuliyeva
*Netherlands Institute of Ecology, Wageningen,
The Netherlands*

Pedro Pena
*Health & Technology Research Center, Lisbon School of
Health Technology, Polytechnic Institute of Lisbon,
Lisbon, Portugal*

Mao Peng
Utrecht University, Utrecht, The Netherlands

Cristiana Pereira
*University of Porto Institute of Public Health, Porto,
Portugal and National Institute of Health Doctor
Ricardo Jorge, Porto, Portugal*

Elena Piecková
*Slovak Medical University in Bratislava, Bratislava,
Slovakia*

Ana C. Pinheiro
*Hercules Laboratory – Cultural Heritage Protection
Studies, Palácio Vimioso, University of Évora, Évora,
Portugal*

Isak S. Pretorius
*ARC Centre of Excellence in Synthetic Biology,
Macquarie University, Sydney, NSW, Australia*

Riina Rautemaa-Richardson
University of Manchester, Manchester, United Kingdom

Malcolm D. Richardson
*Manchester University NHS Foundation Trust,
Manchester, United Kingdom*

Aloia Romani
*Centre of Biological Engineering, University of Minho,
Braga, Portugal*

Karolina Ropejko
Kazimierz Wielki University, Bydgoszcz, Poland

Martin Rühl
*University of Giessen, Giessen, Germany and Fraunhofer
Institute for Molecular Biology and Applied Ecology,
Giessen, Germany*

Raquel Sabino
*Department of Infectious Diseases, National Institute of
Health Dr. Ricardo Jorge, Lisbon, Portugal*

Sonia Salazar-Cerezo
*Westerdijk Fungal Biodiversity Institute, Utrecht,
The Netherlands*

Tulasi Satyanarayana
*Netaji Subhas University of Technology, New Delhi,
India*

Henk A. Schols
*Wageningen University and Research, Wageningen,
The Netherlands*

Esther Segal
Tel Aviv University, Tel-Aviv, Israel

Sílvia Sequeira
*Research Unit VICARTE – Glass and Ceramic for the
Arts, NOVA University Lisbon, Caparica, Portugal*

Marcin Siedlecki
*Research and Innovation Centre Pro-Akademia,
Konstantynów Łódzki, Poland*

Xavier Simon
*French Research and Safety Institute for the Prevention
of Occupational Accidents and Diseases, Vandoeuvre les
Nancy, France*

Kinga Skalska

List of Contributors for Volume	ix
Editor Biographies	xxiii
Preface	xxvii

VOLUME 1

Next Generation Sequencing: Transcriptomics <i>Fabiano Sillo</i>	1
The Cell Wall of Medically Relevant Yeasts and Molds <i>Manuela Gómez-Gaviria, Laura C García-Carnero, Alma K Tamez-Castrellón, and Héctor M Mora-Montes</i>	12
The Fungal Chitinases <i>Georgios Tzelepis and Magnus Karlsson</i>	23
GTPases in Hyphal Growth <i>Bianca Ranocchi and Antonella Amicucci</i>	32
Membrane Transporters, an Overview of the Arbuscular Mycorrhizal Fungal Transportome <i>Nuria Ferrol</i>	44
Fungal Secondary Metabolism <i>Francesco Vinale, Krishnapillai Sivasithamparam, Susanne Zeilinger, and Santiago Gutiérrez</i>	54
Mycotoxins and Mycotoxigenic Fungi: Risk and Management. A Challenge for Future Global Food Safety and Security <i>Claudio Altomare, Antonio F Logrieco, and Antonia Gallo</i>	64
RNA Interference in Fungi <i>Alessandro Silvestri and Luisa Lanfranco</i>	94
The MAP Kinase Network As the Nervous System of Fungi <i>I Correia, D Prieto, R Alonso-Monge, J Pla, and RomanE Román</i>	102
Communication With Plants <i>Marzia Beccaccioli, Valeria Scala, and Massimo Reverberi</i>	114
Genome Evolution of Fungal Plant Pathogens <i>Maria Aragona, Alessandro Infantino, Maria Teresa Valente, Alessandro Grottoli, and Anita Haegi</i>	123
Mycoviruses: A Hidden World Within Fungi <i>Luca Nerva and Walter Chitarra</i>	134
Transposable Elements in Fungi: Coevolution With the Host Genome Shapes, Genome Architecture, Plasticity and Adaptation <i>Cécile Lorrain, Ursula Oggenfuss, Daniel Croll, Sebastien Duplessis, and Eva Stukenbrock</i>	142
Aspergilli, More Than Just Fungi: Shaping the Last Decades of Model Systems <i>Francesca Degola</i>	156
Proteomics in Mycorrhizal and Plant Pathogenic Fungi <i>Federico Vita and Stefano Ghignone</i>	164

Host-Induced Stress Response in Human Pathogenic Fungi <i>Romeu Viana, Pedro Pais, Mafalda Cavalheiro, Mónica Galocha, and Miguel C Teixeira</i>	182
Biodegradation of Aromatic Toxic Pollutants by White Rot Fungi <i>Yitzhak Hadar</i>	197
Fungal Chitin and Chitosan <i>Mostafa M Abo Elsoud</i>	205
Chitin Synthases in Fungi <i>Weiguo Fang</i>	218
Glucose Metabolism and Use of Alternative Carbon Sources in Medically-Important Fungi <i>Shu Yih Chew and Leslie Thian Lung Than</i>	220
Ergosterol Synthesis <i>Somanon Bhattacharya</i>	230
Fungal Volatile Organic Compounds <i>Andrea Martinez and Joan W Bennett</i>	239
Outline of Ascomycota <i>Nalin N Wijayawardene, Kevin D Hyde, and Dong-Qin Dai</i>	246
Structure and Development of Ascomata <i>Chitrabhanu S Bhunjun, Chayanard Phukhamsakda, and Kevin D Hyde</i>	255
Laboulbeniomycetes, Enigmatic Fungi With a Turbulent Taxonomic History <i>Danny Haelewaters, Michał Gorczak, Patricia Kaishian, André De Kesel, and Meredith Blackwell</i>	263
Phylogenetic Advances in Leotiomycetes, an Understudied Clade of Taxonomically and Ecologically Diverse Fungi <i>C Alisha Quandt and Danny Haelewaters</i>	284
Pezizomycetes <i>Donald H Pfister and Rosanne Healy</i>	295
Outline of Basidiomycota <i>Mao-Qiang He and Rui-Lin Zhao</i>	310
<i>Cantharellales</i> Gäum <i>Ibai Olariaga</i>	320
Boletales <i>Matteo Gelardi</i>	329
Functional Traits of Stipitate Basidiomycetes <i>Hans Halbwachs and Claus Bässler</i>	361
Fossil Ascomycota and Basidiomycota, With Notes on Fossil Lichens and Nematophytes <i>Hans Halbwachs, Carla J Harper, and Michael Krings</i>	378
The Cultivation of Macrofungi <i>Simone Di Piazza, Grazia Cecchi, Ester Rosa, and Mirca Zotti</i>	396
Macrofungi as Food <i>Peter E Mortimer, Eric Boa, Kevin D Hyde, and Huili Li</i>	405
Overview: Human Fungal Pathogens <i>Sirida Youngchim and Joshua D Nosanchuk</i>	418
Polyenes and Amphotericin B <i>Irene García-Barbazán and Óscar Zaragoza</i>	421
Azole Antifungal Drugs: Mode of Action and Resistance <i>Rocio Garcia-Rubio, Maria C Monteiro, and Emilia Mellado</i>	427

Echinocandins <i>Alexander J Lepak and David R Andes</i>	438
Allylamines, Morpholine Derivatives, Fluoropyrimidines, and Griseofulvin <i>Kelly Ishida and Vinícius de Moraes Barroso</i>	449
New Targets for the Development of Antifungal Agents <i>Cristina de Castro Spadari, Taissa Vila, Vinícius de Moraes Barroso, and Kelly Ishida</i>	456
Immunotherapy of Fungal Infections <i>Kausik Datta and Liise-Anne Pirofski</i>	468
Diagnosis of Fungal Infections <i>María J Buitrago and Clara Valero</i>	498
Commensal to Pathogen Transition of <i>Candida albicans</i> <i>Ilse D Jacobsen, Maria J Niemiec, Mario Kapitan, and Melanie Polke</i>	507
<i>Candida psilosis</i> Complex <i>Tibor M Nemeth, Attila Gacser, and Joshua D Nosanchuk</i>	526
<i>Candida auris</i> : A New, Threatening Yeast <i>Javier Pemán and Alba Ruiz-Gaitán</i>	544
Immune Response to <i>Candida albicans</i> Infection <i>Alberto Yáñez, Celia Murciano, M Luisa Gil, and Daniel Gozalbo</i>	556
Infections by <i>Cryptococcus</i> species <i>Suélen A Rossi and Oscar Zaragoza</i>	576
Epidemiology of Infections Caused by Molds <i>Jennifer M Cuellar-Rodriguez and Luis Ostrosky-Zeichner</i>	584
Diseases Caused by <i>Aspergillus fumigatus</i> <i>Rocio Garcia-Rubio and Laura Alcazar-Fuoli</i>	591
Mucormycosis <i>Priya Uppuluri, Abdullah Alqarihi, and Ashraf S Ibrahim</i>	600
Epidemiology of Dimorphic Fungi <i>Ana CO Souza and Carlos P Taborda</i>	613
Histoplasma <i>Joshua D Nosanchuk, Daniel Zamith-Miranda, and Allan J Guimarães</i>	624
Coccidioidomycosis: The Valley Fever <i>Hazael Hernandez and Luis R Martinez</i>	629
<i>Blastomyces</i> and Blastomycosis <i>Bruce S Klein, Joseph A McBride, and Gregory M Gauthier</i>	638
Paracoccidioidomycosis <i>Carlos P Taborda, Luiz R Travassos, and Gil Benard</i>	654
Sporotrichosis <i>Rodrigo Almeida-Paes, Maria C Gutierrez-Galhardo, and Rosely M Zancopé-Oliveira</i>	676
Advances in Genomics Research of <i>Pneumocystis</i> Species <i>Aleksey Porollo and Melanie T Cushion</i>	687
Subcutaneous Fungal Infections <i>Dayvison FS Freitas, Priscila M de Macedo, Maria C Gutierrez-Galhardo, and Fábio Francesconi</i>	695
Superficial Infections of the Skin and Nails <i>Priscila M de Macedo and Dayvison FS Freitas</i>	707

Genitourinary Fungal Infections (Other Than Vaginal Candidiasis) <i>Sutthichai Sae-Tia and Bettina C Fries</i>	719
Oropharyngeal and Vulvovaginal Candidiasis <i>Margaret E McCort</i>	726
Fungal Infections of Human Mammary Gland During Lactation <i>Katarzyna Łubiech and Magdalena Twarużek</i>	730
Fungal Infections of the Central Nervous System <i>Haroldo C de Oliveira, Rafael F Castelli, Diogo Kuczera, Taiane N Souza, Caroline M Marcos, Liliana Scorzoni, Leonardo Nimrichter, and Marcio L Rodrigues</i>	736
Fungal Cardiac Infections <i>Sichen Liu and Joshua D Nosanchuk</i>	749
Fungal Ophthalmological Infections <i>Daniel J Polla and Joann J Kang</i>	757
AIDS-Related Mycoses <i>Tihana Bicanic, Clare Logan, Beatriz L Gomez, Thuy Le, and Sean Wasserman</i>	763
Fungal Infections in Transplant Recipients <i>Jeremy S Nel, Anne Lachiewicz, and David Van Duin</i>	781
Fungal Infections in Cancer Patients <i>Bruno P Granwehr and Dimitrios P Kontoyiannis</i>	792
Fungal Infections in the Setting of Biological Therapies (in the Non-Transplant Host) <i>Michail S Lionakis</i>	803
Uncommon Yeasts and Molds Causing Human Disease <i>Christopher J Shoff and John R Perfect</i>	813
Fungal Infections in Children <i>Sandra Guerguis, Philip Lee, and David L Goldman</i>	835

VOLUME 2

Exposure to Fungi in Health Care Facilities <i>Raquel Sabino</i>	1
Elderly Exposure to Fungi: A Review Study <i>Marina Almeida-Silva and Cristiana Pereira</i>	11
Integrating Fungi in the Drinking Water Regulation and in Guidelines for Materials in Contact With Drinking Water. Is there Room for Change? <i>Monika Novak Babič, João Brandão, and Nina Gunde-Cimerman</i>	16
Mycological Studies in Cultural Heritage <i>Ana C Pinheiro and Sílvia Sequeira</i>	27
How to Assess Fungal Contamination in School Environments <i>Beatriz de Almeida and Carla Viegas</i>	40
Airborne Fungi in Workplace Atmospheres: Overview of Active Sampling and Offline Analysis Methods Used in 2009–2019 <i>Xavier Simon and Pauline Loison</i>	49
Fungal Contamination of Sawmills <i>Anne Straumfors and Anani Afanou</i>	59

Next-Generation Sequencing in Environmental Mycology. A Useful Tool? <i>Hamza Mbareche</i>	73
Fungal Contamination of Swimming Pools and Fitness Centers <i>Beatriz Almeida and Carla Viegas</i>	84
Occupational Fungal Exposure and Assessment on Animal Production <i>Marta Dias, Pedro Sousa, and Carla Viegas</i>	91
Fungal Prevalence on Waste Industry – Literature Review <i>Marta Dias and Carla Viegas</i>	99
<i>Aspergillus</i> in Indoor Environments <i>Malcolm D Richardson and Riina Rautemaa-Richardson</i>	107
Fungal Exposure in Agricultural Environments – A Review <i>Pedro Sousa and Carla Viegas</i>	116
Fungal Contamination of Beaches <i>Esther Segal and Daniel Elad</i>	125
Fungal Exposure and Relevant Recreational Settings <i>João Brandão, Chelsea Weiskerger, and Monika Novak Babič</i>	130
Assessment of <i>Aspergillus</i> Section <i>Fumigati</i> in Occupational Environments – A Bibliographic Review <i>Pedro Sousa and Carla Viegas</i>	139
Screening of Fungal Azole Resistance in Different Environmental Samples <i>Pedro Pena, Joana Morais, Liliana A Caetano, and Carla Viegas</i>	150
Assessment of Azole Resistance in Healthcare Facilities <i>Liliana Aranha Caetano, Natália Costa, and Cátia Oliveira</i>	159
Climate Change and Aflatoxins Contamination in the Iberian Peninsula <i>Ricardo Assunção, Ariane Vettorazzi, Elena González-Peñas, and Carla Martins</i>	168
The Usefulness of Human Biomonitoring in the Case of Mycotoxins Exposure Assessment <i>Susana Viegas and Carla Martins</i>	176
Mycotoxins as Endocrine Disruptors – An Emerging Threat <i>Carla Martins, Arnau Vidal, Marthe De Boevre, and Ricardo Assunção</i>	180
Fungi in Milk and in Dairy Products <i>Karolina Ropejko, Jan Grajewski, and Magdalena Twarużek</i>	193
Profile of Fungi in Dietary Supplement, Based on Plant Raw Material <i>Iwona Altyn and Magdalena Twarużek</i>	201
Molds in Food Spoilage <i>Magdalena Twarużek, Ewelina Soszczyńska, and Justyna Kwiatkowska-Giżyńska</i>	208
Mycobiota Causing Diseases in Pets <i>Elena Piecková</i>	215
Production of Native and Recombinant Enzymes by Fungi for Industrial Applications <i>Jean-Paul Ouedraogo and Adrian Tsang</i>	222
Fungal Laccases as Biocatalysts for Wide Range Applications <i>Felipe de Salas and Susana Camarero</i>	233
Fungal Lignin-Modifying Peroxidases and H ₂ O ₂ -Producing Enzymes <i>Mii R Mäkelä, Kristiina S Hildén, and Jaana Kuuskeri</i>	247
Fungal Peroxygenases – A Versatile Tool for Biocatalysis <i>René Ullrich, Alexander Karich, and Martin Hofrichter</i>	260

Fungal Lytic Polysaccharide Monooxygenases (LPMOs): Biological Importance and Applications <i>Anikó Várnai, Olav A Hegnar, Svein J Horn, Vincent GH Eijssink, and Jean-Guy Berrin</i>	281
Applications of Fungal Cellulases <i>Astrid Müller, Joanna E Kowalczyk, and Miia R Mäkelä</i>	295
Applications of Fungal Hemicellulases <i>Uttam Kumar Jana and Naveen Kango</i>	305
Applications of Fungal Pectinases <i>María G Zavala-Páramo, María G Villa-Rivera, Alicia Lara-Márquez, Everardo López-Romero, and Horacio Cano-Camacho</i>	316
Fungal Biotechnology: Fungal Amylases and Their Applications <i>Rosemary A Cripwell, Willem Heber van Zyl, and Marinda Viljoen-Bloom</i>	326
Applications of Fungal Inulinases <i>Ritumbhara Choukade and Naveen Kango</i>	337
Fungal Proteases: Current and Potential Industrial Applications <i>Aleksandrina Patyshakuliyeva</i>	348
Multifarious Applications of Fungal Phytases <i>Parvinder Kaur, Ashima Vohra, and Tulasi Satyanarayana</i>	358
Modification of Plant Carbohydrates Using Fungal Enzymes <i>Mirjam A Kabel, Matthias Frommhagen, Peicheng Sun, and Henk A Schols</i>	370
Production of Oligosaccharides by Fungi or Fungal Enzymes <i>Maíra N de Almeida and Gabriela P Maitan-Alfenas</i>	385
Metabolic Modeling of Fungi <i>Sebastián N Mendoza, Sara Calhoun, Bas Teusink, and María Victoria Aguilar-Pontes</i>	394
Production of Organic Acids by Fungi <i>Levente Karaffa and Christian P Kubicek</i>	406
Biotechnological Advancements, Innovations and Challenges for Sustainable Xylitol Production by Yeast <i>Sara L Baptista, Aloia Romaní, and Lucília Domingues</i>	420
Biotechnology of Wine Yeasts <i>Niël van Wyk, Christian von Wallbrunn, Jan H Swiegers, and Isak S Pretorius</i>	428
Ethanol Tolerance and Production by Yeasts <i>Sandra Garrigues and Sonia Salazar-Cerezo</i>	447
The Biosynthesis of Fungal Secondary Metabolites: From Fundamentals to Biotechnological Applications <i>Olga Mosunova, Jorge C Navarro-Muñoz, and Jérôme Collemare</i>	458
Degradation of Homocyclic Aromatic Compounds by Fungi <i>Ronnie JM Lubbers and Ronald P de Vries</i>	477
Genetic Engineering for Strain Improvement in Filamentous Fungi <i>Sandra Garrigues, Natalia Martínez-Reyes, and Ronald P de Vries</i>	489
Strain Improvement and Genetic Engineering of <i>Trichoderma</i> for Industrial Applications <i>Peijie Chen, Guan Pang, Feng Cai, and Irina S Druzhinina</i>	505
Expression of Recombinant Fungal Proteins in <i>Pichia Pastoris</i> <i>Naoki Sunagawa and Kiyohiko Igarashi</i>	518
Transcriptional Regulation: How Saprobic Fungi Tune the Production of Plant Cell Wall Degrading Enzymes <i>Joanna E Kowalczyk and Paul Daly</i>	528

Bioinformatics Approaches for Fungal Biotechnology <i>Jiajia Li, Ronald P de Vries, and Mao Peng</i>	536
Production of Biofuels From Biomass by Fungi <i>Eva Ottum, Scott E Baker, and Erin L Bredeweg</i>	555
Oleaginous Fungi in Biorefineries <i>Shousong Zhu, Gregory Bonito, Yinhua Chen, and Zhi-Yan Du</i>	577
Role of Fungi in Fermented Foods <i>Garima Maheshwari, Jenny Ahlborn, and Martin Rühl</i>	590
The Application of Fungal Biomass as Feed <i>Sajjad Karimi, Jorge A Ferreira, and Mohammad J Taherzadeh</i>	601
Applications of Fungal Polysaccharides <i>Monika Osińska-Jaroszuk, Justyna Sulej, Magdalena Jaszek, and Jolanta Jaroszuk-Ścisiel</i>	613
Development of Mycoherbicides <i>Alexander Berestetskiy</i>	629
Biofungicides: An Eco-Friendly Approach for Plant Disease Management <i>Ana C dos Santos Gomes, Ronivaldo R da Silva, Silvino I Moreira, Samara NC Vicentini, and Paulo C Ceresini</i>	641
Degradation of Plastics by Fungi <i>Wolfgang Zimmermann</i>	650
Treatment of Industrial Wastewaters and Liquid Waste by Fungi <i>Karina Michalska, Anna Goszkiewicz, Kinga Skalska, Eliza Kołodziejczyk, Justyna Markiewicz, Rafał Majzer, and Marcin Siedlecki</i>	662
Antitumor and Immunomodulatory Compounds from Fungi <i>Rosario Nicoletti</i>	683
Mycelium Materials <i>Freek VW Appels and Han AB Wösten</i>	710
Subject Index	719

Exposure to Fungi in Health Care Facilities

Epidemiology of Nosocomial Fungal Infections

Fungal diseases affect over a billion people across the globe (Bongomin *et al.*, 2017) and are an increasingly common cause of morbidity and mortality in hospitalized patients. There are multiple factors that predispose to the development of these infections such as neutropenia, stem cell transplantation, hypogammaglobulinemia, T-cell dysfunction, and/or mucosal damage. Gastro-intestinal surgery or other extensive surgeries, use of invasive medical devices, high exposure to antibiotics, diabetes, corticosteroid therapy, prolonged hospitalization, and interinstitutional transfer of patients are other risk factors for the development of fungal infections (Fridkin and Jarvis, 1996; de La Rosa *et al.*, 2002; Sadfar and Maki, 2002; McCarty and Pappas, 2016). Healthcare-associated invasive fungal infection (IFI) outbreaks have been increasing in immunocompromised patients and are associated to suboptimal hospital environmental conditions, transmission via healthcare workers' hands, contaminated medical products, and transplantation of infected organs (Benedict *et al.*, 2017).

Significant statistical associations are often found between the degree of fungal contamination of air and hospital surfaces and the number of fungal infections in hospitalized immunocompromised patients (Kanamori *et al.*, 2015). When an imbalance occurs between the patient's immune system and the surrounding environment fungal infections are more likely to arise. In hospital units with immunocompromised patients, environmental quality (fungal burden and species) plays a key role in the development of infection.

In a "One Health" approach, which is aimed at designing and improving strategies, actions, legislation, and research that involves multiple sectors for achieving better public health outcomes, healthcare facilities have a great impact in health promotion among the several issues that affect the quality of population health (Gola *et al.*, 2019).

In fact, hospital environment plays a crucial role in the epidemiology of fungal infections. The majority of nosocomial fungal outbreaks occurred in patients exposed to building environments with inadequate air filtration, ongoing construction, water damage, and air pressure differentials (Benedict *et al.*, 2017).

Airborne infection is considered a major route of transmission in hospitals, and prevention of airborne pathogens is critically important to control hospital infections (Tong *et al.*, 2017). According to some studies (Srikanth *et al.*, 2008; Viegas *et al.*, 2016), air sampling is not sufficient to assess the risk of fungal infection in a hospital environment as airborne fungal particles eventually settle on surfaces and sampling is essential to identify potential risks and sources of contamination. The most frequent sources of fungal contamination within hospital environment are air-conditioning and ventilation systems, particles, ornamental plants, flowers, fresh fruits, food, water, construction work in and around hospital buildings, occupants or visitors, or even insects (Kordbacheh *et al.*, 2005; Pantoja *et al.*, 2009). Therapeutic swimming pools and nebulizers have also been pointed out as possible sources of nosocomial fungal infections (Angenent *et al.*, 2005; Peckham *et al.*, 2016). The degree of environmental fungal contamination can further increase dramatically in combination with other factors such as the presence of a favorable microclimate (humidity and temperature) and other geoclimatic factors (as the season of the year), the population density within a specific hospital/ward, and developed activities, among others. In the hospital setting, modes of transmission and portals of entry for the etiological agents responsible for nosocomial fungal infections vary according to the pathogen involved. Fungal infection may occur by direct or indirect contact with contaminated surfaces or objects, through the hands of health professionals, by ingestion and by inhalation of contaminated particles or bioaerosols (Leung and Chan, 2006; Sabino, 2015).

The epidemiology of IFIs in immunocompromised patients is rapidly changing due to several factors, namely the advances in medical care. Moreover, global warming (including climatic oscillations) may select for environmental species that have acquired thermotolerance, a key step toward pathogenesis to humans. In addition, important virulence factors have developed in environmental fungi, because they are essential for yeast survival in the environment. Thus, fungi traditionally regarded as non-pathogenic to humans have virulence factors similar to those of their pathogenic relatives (Richardson and Lass-Flörl, 2008; Kanamori *et al.*, 2015; de S Araújo *et al.*, 2017).

Aspergillus and *Candida* species are responsible for most nosocomial fungal infections in immunocompromised patients. However, other fungi have emerged as agents of nosocomial fungal infection, namely *Fusarium* species, *Pseudallescheria boydii*, species belonging to the subphylum Mucormicotina, and yeasts like *Malassezia* or *Saccharomyces*. Table 1 shows the most frequent opportunistic fungal species, associated with nosocomial infections. Some of these emerging pathogens are, in some cases, resistant to the available antifungals, potentiating the threat of novel fungal diseases (de S Araújo *et al.*, 2017).

The most common potentially pathogenic fungi can survive and persist in bioaerosols and surfaces for many days or even months and can therefore be a constant source of transmission.

As nosocomial fungal infections progress rapidly and fungi are increasingly resistant to available antifungal agents, efforts are urgently needed for infection prevention, early diagnosis, and effective treatment. Preventive measures are of great importance in the control of nosocomial fungal infections, and should include environmental surveillance and strict application of cleaning procedures. Training health professionals and improving their knowledge of fungal infections is also of particular importance in preventing and controlling nosocomial fungal infections (Neely and Orloff, 2001).

Table 1 Most frequent fungal species associated with nosocomial infections

Yeasts	<i>C. albicans</i>	Yeast-like fungi	<i>Trichosporon</i> spp.
	<i>Candida auris</i>		<i>Geotrichum</i> spp.
	<i>C. glabrata</i> (complex)		
	<i>C. parapsilosis</i> (complex)		
	<i>C. tropicalis</i>		
	<i>Pichia kudriavzevii</i>	Subphylum Mucormicotina	<i>Lichtheimia corymbifera</i>
	<i>Merozoma guilliermondii</i>		<i>Cunninghamella</i> spp.
	<i>Malassezia</i> spp.		<i>Mucor</i> spp.
	<i>Rhodotorula</i> spp.		<i>Rhizopus</i> spp.
	<i>Saccharomyces</i> spp.		<i>Rhizomucor</i> spp.
<i>Aspergillus</i> spp.	<i>A. fumigatus</i> (section)		
	<i>A. niger</i> (section)		
	<i>A. terreus</i> (section)		
	<i>A. flavus</i> (section)		
Other hyaline molds	<i>Sarocladium</i> spp.	Dematiaceous molds	<i>Alternaria</i> spp.
	<i>Fusarium</i> spp.		<i>Bipolaris</i> spp.
	<i>Paecilomyces</i> spp.		<i>Curvularia</i> spp.
	<i>Purpureocillium lilacinus</i>		<i>Exophiala</i> spp.
	<i>Scedosporium</i> spp.		
	<i>Pseudallesheria boydii</i>		

Note: Adapted from Richardson, M., Lass-Flörl, C., 2008. Changing epidemiology of systemic fungal infections. Clin. Microbiol. Infect. 14 (Suppl 4), 5–24. doi:10.1111/j.1469-0691.2008.01978.x. Alangaden, G.J., 2011. Nosocomial fungal infections: Epidemiology, infection control, and prevention. Infect. Dis. Clin. North Am. 25 (1), 201–225. doi:10.1016/j.idc.2010.11.003. Bounoux, M.E., Brun, S., Zahar, J.-R., 2018. Healthcare-associated fungal outbreaks: New and uncommon species, New molecular tools for investigation and prevention. Antimicrob. Resist. Infect. Control 7, 45. doi:10.1186/s13756-018-0338-9.

About 20%–50% of hematological patients show evidence of IFI at autopsy (Traoré *et al.*, 2002). The mortality attributed to *Candida* systemic infections ranges from 8% to 53% in allogeneic bone marrow transplant recipients, while in the spread of filamentous fungi such as *Aspergillus*, *Fusarium*, and infections caused by fungi belonging the subphylum Mucormicotina this rate ranges from 56% to 95% (Martino *et al.*, 2002; Fukuda *et al.*, 2003; Roden *et al.*, 2005).

In the following pages, the most frequent fungal genera and species associated with nosocomial fungal infections will be discussed in more detail.

Candida

Infections caused by yeasts belonging to *Candida* genus are classified as candidiasis (includes candidemia). From 150 *Candida* species described, some are part of our normal microbiota and only 10% are known to be responsible for infections in humans, *C. albicans* being the most frequent etiological agent (Yapar, 2014). Nosocomial bloodstream infections caused by *Candida* species have increased in recent decades, mainly due to the multiple medical resources currently used, such as chemotherapy, antibiotics, catheters, and parenteral nutrition (Perlroth *et al.*, 2007; Safdar *et al.*, 2001; Pemán *et al.*, 2004; Bedini *et al.*, 2006; Pfaller and Diekema, 2007). In an European study (European Centre for Disease Prevention and Control, 2013a), *Candida* sp. was the 5th most common microorganism isolated from bloodstream infections (7.4% isolates).

Among invasive candidiasis, candidemia is estimated to account for 2–8 infections per 10,000 hospital discharges in recent studies from the United States and Europe (Alangaden, 2011). The true incidence of healthcare-associated candidemia is likely to be since approximately 50% of blood culture are negative (Alangaden, 2011).

Although *C. albicans* remains the most frequently isolated species, numerous studies have detected changes in the epidemiology of these infections, with a significant increase in the number of infections caused by non-*albicans* species, namely *C. tropicalis* and *C. parapsilosis* (complex), *C. glabrata* (complex), and *Pichia kudriavzevii* (former *C. krusei*) (Safdar *et al.*, 2001; Capoor *et al.*, 2005; Almirante *et al.*, 2005). Some studies mention that non-*albicans* species are the cause of two-thirds of candidemia cases (Posteraro *et al.*, 2015). One of the main reasons for this rising is the introduction of fluconazole prophylaxis/therapy, which led to the positive selection of azole-less susceptible/resistant species (Berkow and Lockhart, 2017). *Candida* sp. can be found temporarily or permanently in the gastrointestinal tract in about 40%–50% of the healthy adult population (Eggimann *et al.*, 2003) and in the genital tract of about 20% of healthy women (Sobel, 2005). Although *Candida* sp. does not constitute the normal flora of the skin, it may transiently colonize fingers or skin folds (Trofa *et al.*, 2008).

The longer length of hospital stay, the greater chance of *Candida* colonization, given the longer exposure to risk factors. A previous colonization by *Candida* spp. has been reported as an important risk factor for the development of systemic infection (Pittet *et al.*, 1994; Dalle *et al.*, 2008). Inanimate environmental surfaces and the colonized patients themselves may constitute a

reservoir from which other patients can acquire the fungus and, in some cases, develop candidemia (Hota, 2004; Stephan *et al.*, 2002). Systemic infection caused by *C. albicans* and *C. tropicalis* is usually preceded by colonization (endogenous transmission), while invasive disease caused by *C. parapsilosis* may occur without prior colonization and is often transmitted horizontally from contaminated external sources (exogenous transmission), such as infusions, parenteral feeding, catheters, prostheses, or hands of health professionals or visitors (Weems *et al.*, 1987; Raad and Bodey, 1992; Levin *et al.*, 1998; Lupetti *et al.*, 2002; Kan *et al.*, 2002; Deshpande, 2003; San-Miguel *et al.*, 2004; van Asbeck *et al.*, 2007; Trofa *et al.*, 2008).

Candida parapsilosis is associated with approximately 25% of *Candida* infections in European hospitals, and it is now the second most commonly isolated *Candida* species from blood cultures in Europe, Canada, and Latin America (Trofa *et al.*, 2008; Sabino *et al.*, 2010a). This species is often described as responsible for nosocomial outbreaks and may be a frequent agent of candidemia. This species survives on surfaces for long periods of time (more than 14 days) and is able to form biofilms, allowing a high survival capacity in a hospital setting. Cell surface hydrophobicity has been associated with the initial adherence of *C. parapsilosis* to surfaces (Panagoda *et al.*, 2001), and the production of slime has been linked to the tendency of *C. parapsilosis* to adhere to the surfaces of intravascular plastic catheters and prosthetic devices (Raad and Bodey, 1992; Panagoda *et al.*, 2001). Adherence to tissues or medical devices precedes the biofilm formation, presumably resulting in a change in organism morphology and behavior (Trofa *et al.*, 2008). Biofilm-forming potential is cited as a reason that patients with *C. parapsilosis*-infected catheters should have the device removed (Barchiesi *et al.*, 2016) because the ability to grow as a biofilm is directly related to clinically significant disease.

For a better understanding of its epidemiology, several typing methods are used and microsatellite analysis has been reported as highly discriminant (Sabino *et al.*, 2010b; Vaz *et al.*, 2011; Reiss *et al.*, 2012; Diab-Elschahawi *et al.*, 2012; Romeo *et al.*, 2013; Barchiesi *et al.*, 2016). Analysis of *C. parapsilosis* isolates from hospital environment showed great genotypic diversity; however, the same or very similar genotypes were also found, suggesting that environment could be the source of some strains and that infections due to *C. parapsilosis* may be mainly related with exogenous transmission to the patient.

Recently, *C. auris* emerged as an etiological agent of candidemia. This species has been associated with hospital environments, being found in several different hospital surfaces, where it can survive for long periods. This species may be resistant to various classes of antifungals and is associated with high mortality in patients, given the limited treatment options (Chatterjee *et al.*, 2015). *C. auris* has a high propensity for patient-to-patient transmission, probably related to contamination of the hospital environment or transient colonization of medical devices, equipment, or people. *C. auris* can persist on surfaces in healthcare environments. *C. auris* has been cultured from multiple locations in patient rooms, including both high-touch surfaces, such as bedside tables and bedrails, and general environmental surfaces farther away from the patient, such as windowsills. *C. auris* has also been identified on mobile equipment that is shared between patients, such as glucometers, temperature probes, blood pressure cuffs, ultrasound machines, nursing carts, and crash carts (see “Relevant Websites section”). This multidrug-resistant species is rapidly spreading worldwide, with several described outbreaks. One of those was found to be linked to reusable axillary temperature probes (Eyre *et al.*, 2018). The role of healthcare workers in spreading *C. auris* is still unknown. However, during investigation of the outbreak in the United Kingdom, *C. auris* was isolated from the nares of a nurse who was providing care for a patient who was heavily colonized (Schelenz *et al.*, 2016). Moreover, an outbreak investigation in Colombia isolated *C. auris* from the hands of two healthcare workers and the groin of one out of six healthcare workers. Whole-genome sequencing (WGS) established that these were genetically identical to strains isolated from a patient and surround environment (Escandón *et al.*, 2019). It is a species of difficult identification since it can be confused with other yeasts species (*C. haemulonii*, *C. sake*, *Rhodotorula glutinis*, *Saccharomyces cerevisiae*, or other non-*albicans* *Candida* species). Correct species identification is achieved through biochemical or mass spectrometry methods, whose devices already have their databases updated, that is, they already contain this species’ profile. Confirmation of species identification should be done by sequencing specific DNA regions (as the D1/D2 region of ribosomal DNA) or specific polymerase chain reaction targeted to *C. auris*.

Difficulties with laboratory identification and lack of knowledge about this new species may result in potential dissemination of this microorganism and lack of awareness of outbreaks that may exist.

Given the highlighted questions raised with this new species, special recommendations regarding infection control measures in healthcare settings have been produced, such as (see “Relevant Websites section”):

- Adherence to hand hygiene.
- Appropriate use of transmission-based precautions based on setting.
- Application of all defined precautions for contact transmission.
- Considerations for single rooms and roommate pairings for people on contact precautions, which might be considered based on a single pathogen (as *C. auris*) without regard to cocolonizing organisms as a measure to control transmission during an acute outbreak.
- Cleaning and disinfecting the patient care environment (daily and terminal cleaning) and reusable equipment with recommended products and on a more frequent schedule.
- Follow all manufacturers’ directions for use of surface disinfectants and applying the product for the correct contact time. Some products with fungicidal activity may not be effective against *C. auris*, and products solely dependent on quaternary ammonia compounds are not effective.
- Interfacility communication about patient’s *C. auris* status when a patient is transferred to another healthcare facility, namely nursing homes.

- Screening contacts of newly identified case patients to identify *C. auris* colonization.
- Laboratory surveillance of clinical specimens to detect additional cases.
- Change protective equipment (if worn) and performing hand hygiene when moving between roommates.

Aspergillus

The filamentous fungi most frequently associated with hospital infections is *Aspergillus*, especially in patients from hematological and bone marrow transplant wards. *Aspergillus* conidia are very small and easily inhalable and can colonize the upper and lower respiratory tract (Walsh *et al.*, 2008).

Worldwide, it is estimated that over 30 million of patients are at risk of developing invasive aspergillosis due to the use of corticosteroids and/or other immunosuppressive therapies and that about ~250,000 persons will develop the disease annually. Diagnosis is difficult and often too late. The associated mortality is 50% if the infection is treated and >99% if not treated (see “Relevant Websites section”). The most frequently *Aspergillus* sections isolated from clinical settings are *Fumigati*, *Flavi*, *Nigri*, and *Nidulantes*, which are also the most frequent in the environment (Warris *et al.*, 2001). Invasive aspergillosis generally involves inhalation of conidia or hyphae and further growth in human internal milieu. Vonberg and Gastmeier (2006) reviewed all cases of invasive aspergillosis and concluded that *Aspergillus* is able to cause disease in environments with less than 1 colony-forming unit m^{-3} of air. They recommended that at-risk patients should not be exposed to *Aspergillus* and concluded that prevention from all routes is critical (see “Relevant Websites section”).

A significant association was found between *Aspergillus* isolates of the patient’s room and *Aspergillus* isolates colonizing the respiratory tract of lung transplant recipients (Bonnal *et al.*, 2015), emphasizing the environmental risk of contamination within hospital wards.

One key concern is the risk of aspergillosis associated with hospital construction. In a previous review, construction work accounted for about half (49%) of the causes of hospital-acquired aspergillosis outbreaks (Vonberg and Gastmeier, 2006). Accordingly, there have been many efforts to control environmental fungal contamination using appropriate ventilation systems, such as high-efficiency particulate air filters (Sehulster *et al.*, 2004; Benet *et al.*, 2007; Kanamori *et al.*, 2015). Routine air sampling is not recommended; however, where major works are to be undertaken it may be useful to establish baseline levels of *Aspergillus* in the air and continue to monitor during construction work to detect increased counts, which should prompt additional preventive measures (Sehulster *et al.*, 2004).

Infection control practitioners must consider some key factors when addressing land excavation and building demolition. To minimize the risk of fungal infection and contamination of the healthcare environment during the demolition, excavation, and construction phases of the build, infection control risk assessments must be undertaken prior to commencement and as needed during the build. Such risk assessments document the type of build, the risk category in relation to patients and departments, and the class of barriers required throughout each phase of the works. Major construction and/or renovation activities require the establishment of a multidisciplinary team including but not limited to the healthcare facility major projects manager, hospitals engineer, infection prevention and control, clinical and department managers, environmental services manager, and architects and contracted building supervisors (Harrington, 2016).

Traditionally, clinical microbiology laboratories have relied heavily on morphology-based identification methods to differentiate *Aspergillus* species. This allowed several genetically distinct species to be misidentified (Balajee *et al.*, 2007, 2009). In fact, many species share morphological features and can only be identified by sequencing specific genes, which has led to the clustering of species with overlapping morphologies into sections.

Thus, with the development of molecular tools, the number of *Aspergillus* species involved in human infections is continuously increasing.

Aspergillus Fumigati section, composed of *A. fumigatus* sensu stricto and its cryptic species, is the most frequent isolated *Aspergillus* section in clinical products and is also often isolated from environmental sources. Antifungal resistance in *A. fumigatus* is emerging (European Centre for Disease Prevention and Control, 2013b) and reduced susceptibility is associated with higher mortality (Verweij *et al.*, 2016). In *A. fumigatus*, *cyp51A* gene encodes lanosterol 14- α -sterol demethylase, which is required for the biosynthesis of ergosterol, an essential component of the fungal cell membrane and mutations in this gene and its promoter are in the basis of the triazole resistance. Numerous mutations in *cyp51A* have been reported that confer resistance to triazoles *in vitro*.

Reasons for the increased resistance include the use of prophylactic antifungals/treatment with azoles, and the use of agricultural azoles (Verweij *et al.*, 2016). The molecular basis of resistance to triazoles in *A. fumigatus* mainly involves the occurrence of non-synonymous mutations in the *cyp51A* gene that cause structural alterations due to amino acid substitutions and are sufficient to induce resistance to some or all triazole drugs. These resistant mutations often evolve during prolonged azole treatment in patients with chronic forms of aspergillosis (Hagiwara *et al.*, 2016). On the other hand, other mutations are linked to environmental transmission; the environmentally driven polymorphism TR34/L98H consists of a tandem repeat (TR) of 34 bases in the promoter of the *cyp51A* gene and a leucine-to-histidine change at codon 98 (Mellado *et al.*, 2007); this polymorphism is globally widespread in environmental and clinical isolates (Chowdhary *et al.*, 2015, 2017). Another *cyp51A* -mediated resistance alteration that leads to high-level voriconazole resistance, TR46/Y121F/T289A, has also been described in *A. fumigatus* (van der Linden *et al.*, 2013).

The inhalation of antifungal-resistant isolates of environmental origin is currently a major concern of the scientific community (Chowdhary *et al.*, 2015, 2017). Resistance to triazoles may severely limit treatment options and has been associated with poor

prognosis regarding the course of the infection (Snelders *et al.*, 2008; Verweij *et al.*, 2009). In an environmental screening performed by Godeau *et al.* (2019), 83 azole-resistant *A. fumigatus* isolates with a TR34/L98H mutation were obtained from the indoor air, soil, and dust samples of a French hospital. Some studies also suggest differences in virulence of environmental isolates, so appropriate environmental control practices are important for the prevention of nosocomial infections caused by *Aspergillus*. The European Centre for Disease Prevention and Control (2013b) recommended to improve epidemiological surveillance, to develop molecular methods to detect triazole resistance, and to investigate the environmental origin of *A. fumigatus* resistance through environmental and laboratory studies.

In a study performed by Sabino *et al.* (2014), during a one-year period, in four seasonal samplings, air and surfaces samples were collected from the Hematology, Oncology, and ICU wards of a Portuguese Central Hospital. *Aspergillus* was the most frequently recovered fungal genus, followed by *Cladosporium* and *Penicillium*. Antifungal-resistant isolates were also detected, especially cryptic species belonging to the genera *Aspergillus*. In comparison with *Aspergillus* isolates collected from other sources, a significant association was found between different environmental sources and the distribution of different sections, with hospital environment showing greater variability (Sabino *et al.*, 2014). Among the 75 *Aspergillus* isolates from hospital environment, 10 different sections were detected and 25 different species were identified by β -tubulin and calmodulin sequencing, including a high percentage of cryptic species (i.e., not *sensu stricto*) (59%) (Sabino *et al.*, 2016). Although aspergillosis caused by cryptic species remain less frequent than infections caused by “*sensu stricto*” isolates, the eventual high prevalence of cryptic species in hospital environment may change the “regular” antifungal susceptibility profile, increasing the number of resistant strains, which implies a potential danger, especially in wards with immunocompromised patients.

Because of the high mortality rate associated with invasive aspergillosis in vulnerable patients, it is essential to minimize the risks associated to environmental exposure and to understand the biodiversity and concentration of cryptic *Aspergillus* species in air and aerosols, such as those from hospital plumbing. Knowledge of the resistance patterns of *Aspergillus* isolates is important to assess changes in the epidemiology of the organisms studied and to evaluate new therapeutic options.

Mucorales

Mucormycosis is a life-threatening infection by fungi of the order Mucorales, which is associated with mortality rates that exceed 50% (Roden *et al.*, 2005). The agents of mucormycosis are ubiquitous in soil and decaying vegetation, and infection may be acquired by inhalation, ingestion, or contamination of wounds with sporangiospores from the environment (Gonzalez *et al.*, 2002). As with *Aspergillus* species, nosocomial spread of Mucorales may occur by way of air-conditioning systems, particularly during construction (Gonzalez *et al.*, 2002; Roden *et al.*, 2005; Spellberg *et al.*, 2005). According to a review performed by Walther *et al.* (2019), the most common source of outbreaks was contaminated medical devices that are responsible for 40.7% of the outbreaks followed by contaminated air (31.3%). The most prevalent species were *Rhizopus arrhizus* and *R. microsporus* causing 57% of the outbreaks. The genus *Rhizomucor* was dominating in outbreaks related to contaminated air while outbreaks of *Lichtheimia* species and *Mucor circinelloides* were transmitted by direct contact. Outbreaks with the involvement of several species were also reported.

Focal outbreaks of Mucorales have also been associated with the use of contaminated adhesive bandages or tape in surgical wound dressings, resulting in primary cutaneous mucormycosis (Roden *et al.*, 2005; Spellberg *et al.*, 2005). In addition to causing infection in immunocompromised patients, the Mucorales may also cause lethal infections in a broader and more heterogeneous population, such as patients with diabetes, patients receiving deferoxamine therapy, injection drug users, and patients with no apparent immune impairment (Gonzalez *et al.*, 2002). Invasive mucormycosis is clinically similar to aspergillosis and is marked by angioinvasion and tissue infarction (Spellberg *et al.*, 2005). Person-to-person transmission cannot be excluded because Mucorales can sporulate on wounds (Walther *et al.*, 2019).

Nosocomial infections caused by Mucorales have been reviewed (Roden *et al.*, 2005). Clusters of cutaneous infections have occurred in orthopedic and cardiothoracic patients, children with leukemia, and burn patients. These infections were associated with adhesive dressings possibly contaminated with *Rhizopus* and *Lichtheimia* spp. (Gonzalez *et al.*, 2002).

Fusarium

Nosocomial infections caused by members of the genus *Fusarium* have emerged over the past two decades (Pfaller and Diekema, 2010). In the immunocompromised patients, especially those with hematologic malignancies and recipients of allogeneic hematopoietic stem cell transplantation, *Fusarium* can disseminate in the organism causing a systemic and invasive infection (fusariosis) (Nucci and Anaissie, 2007; Pfaller and Diekema, 2010; Lass-Flörl and Cuenca-Estrella, 2017). *Fusarium solani* (complex of species) is the most frequent species involved in fusariosis (50% of cases), followed by *Fusarium oxysporum* (complex of species) (20%), *Fusarium verticillioides* (complex of species), and *Fusarium moniliforme* (complex of species) (10% each). *Fusarium* spp. may show an antifungal susceptibility profile marked by high level of resistance; however, some isolates can be susceptible in vitro to amphotericin B, voriconazole (Alastruey-Izquierdo *et al.*, 2008; Al-Hatmi *et al.*, 2015), notwithstanding, the mortality rate of disseminated fusariosis may exceed 75%.

Most infections are believed to be caused by airborne transmission (Moretti *et al.*, 2018); however, contamination of the water system in the hospital has been reported to result in dispersal of airborne conidia (Anaissie *et al.*, 2001). Water distribution systems in hospitals were identified as potential reservoirs for species of *Fusarium*, where they are thought to be responsible for nosocomial infections (Anaissie *et al.*, 2001; Litvinov *et al.*, 2015). *Fusarium* conidia in water may be aerosolized into the air when the water passes through taps and showers and then inhaled by immunocompromised patients (Anaissie *et al.*, 2001). Since they may be aerosolized into air and inhaled by patients, it is essential to implement prophylactic measures in hospitals to control invasive fusariosis by using filters on taps and showers. DNA sequencing has demonstrated evidence of widespread distribution of clones that were similar to isolates recovered from nosocomial infections in patients (Moretti *et al.*, 2018).

Other Fungi Associated With Hospital Infections

Outbreaks caused by *Scedosporium* spp. have been reported in patients with leukemia undergoing chemotherapy (Alvarez *et al.*, 1995; Ruiz-Diez *et al.*, 1997; Guerrero *et al.*, 2001). Recently, after molecular distinction among species and taxonomic differentiation (Ramirez-Garcia *et al.*, 2018), it was concluded that almost half of the cases of *Scedosporium* spp. infections occurred in immunocompetent hosts, whereas 70% of *Lomentospora prolificans* infections occurred in patients with immunocompromising conditions, mostly malignancy or solid organ transplantation (Seidel *et al.*, 2019). *Lomentospora prolificans* isolates were pan-resistant to virtually all systemically active antifungals, including azoles, terbinafine, and amphotericin B (Seidel *et al.*, 2019).

Paecilomyces and *Purpureocillium* species are of clinical interest because of their pathogenicity and resistance to antifungal agents. *Paecilomyces variotii* is a commonly occurring species in air and food, and it is also associated with many types of human infections, such as fungemia, endocarditis, peritonitis, and osteomyelitis (Williamson *et al.*, 1992; Cohen-Abbo and Edwards, 1995; Chan *et al.*, 1996; Kovac *et al.*, 1998).

In a study performed by Olm *et al.* (2019), *Purpureocillium lilacinum* genomes from infant and neonatal intensive care unit environmental samples shared 99.999% average nucleotide identity, highlighting the potential of hospital-associated fungi to colonize hospitalized infants.

A study performed by Nucci *et al.* (2002), documents the occurrence of nosocomial *Exophiala jeanselmei* fungemia in high-risk patients and confirms the potential role of contaminated water in nosocomial fungal infection. Given the prevalence of *Exophiala* spp. in cystic fibrosis patients' lungs (Grenouillet *et al.*, 2018), the possible transmission of this genus from the hospital environment may be a risk, especially to these patients.

Novel Methods and Future Perspectives

To identify the causative airborne microorganisms, high-volume air samplers have been recently used for collection, and species identification is starting to be performed using a culture-based method but with DNA sequencing analysis as well with the Illumina MiSeq and HiSeq 2000 sequencing systems (WGS) (Tong *et al.*, 2017).

The study of a hospital's metagenome can allow physicians, researchers, and other medical staff a full knowledge of the microbial communities present inside medical wards. This is expected to give information on the presence of certain fungi in highly restricted areas where critical patients are admitted, and therefore to have a considerable impact on public health. Metagenomic strategies are not only an important tool for characterization of the genetic diversity in whole communities, but also represent an indispensable approach for detection of rare fungal taxa (by revealing new Operational taxonomic unit) (see "Relevant Websites section").

For WGS to become applicable for real-time investigations, time and cost of generating and analyzing WGS data need to be reduced. WGS methods are already widely used for investigating bacterial and viral outbreaks. However, most fungal genomes are at least 10 times larger than those of bacteria and viruses; therefore, considerably more time and resources are needed to generate and process fungal genomes. Development of a curated public database containing assembled genomes of major fungal pathogens will significantly accelerate analyses and implementation of WGS into public health by providing reference genomes and control strains for assessing genetic diversity in a population as well as facilitate data sharing among institutions (Litvintseva *et al.*, 2015).

Final Remarks

Fungal infections remain serious and underappreciated causes of illness and death. Much can be done to prevent the consequences of these infections, although environmental exposure to these agents may not be entirely avoidable in the community. Continued public health efforts toward defining, characterizing, and tracking the emergence of fungal infections can help to focus studies on priority infections and settings (Brandt and Park, 2013).

When we focus on fungal contamination in healthcare facilities, we have to think not only of the hospital environment but also of other healthcare facilities, such as nursing homes. In these cases, it is important to emphasize that prevention measures of

healthcare associated fungal infections should be implemented in the same as or similar conditions to in the hospital, to avoid microorganism transmission and dissemination.

Descriptive epidemiology (i.e., detailed assessment of patients' demographic characteristics, clinical histories, and the geographic and temporal distribution of cases) is essential for generating hypotheses about the potential source of infection. For example, cases occurring over several weeks to months and scattered geographically suggest a common source outbreak that involves a widely distributed product, especially when case patients have undergone similar medical treatments (Smith *et al.*, 2013; Mikosz *et al.*, 2014).

To reduce fungal infections in hospital settings, antimicrobial stewardship programs should promote the appropriate use of antimicrobials, leading to better patient outcomes and a reduction in the spread of infections caused by multidrug-resistant fungi. These programs can help educate medical professionals about best practices for continuity of care, following the patient from the inpatient to the outpatient setting. Prevention and infection control strategies are equally important. These would include participating in and leading efforts within the hospital setting to improve antifungal prescribing practices, ensuring that the right antifungal is given to the right patient at the right time. Fungal infections should be a more visible part of the larger national campaign to reduce hospital-acquired and drug-resistant infections. Inpatient infections continue to cause high percentages of avoidable deaths and contribute to waste and high healthcare costs.

Elderly Exposure to Fungi: A Review Study

Marina Almeida-Silva, Centro de Ciências e Tecnologias Nucleares, Instituto Superior Técnico, Universidade de Lisboa, E.N. 10 ao km 139, 7, 2695-066 Bobadela LRS, Portugal and H&TRC-Health & Technology Research Center, ESTeSL-Escola Superior de Tecnologia da Saúde, Instituto Politécnico de Lisboa

Introduction

Indoor air quality is an increasing concern since people spend 90% of their time indoor. The majority of exposure to air pollution happens indoors rather than outdoors, despite the focus being on the latter. Indoor air quality in elderly care centers (ECC) is an emerging important issue arising in the last decade because of the increase of (1) life expectancy, (2) number of individuals residing in ECC, and (3) population aging, which is correlated with the inversion of the age pyramid (United Nations UN, 2012; GEP/MSSS, 2010). However, given the magnitude of the ECC population that is ageing, and the considerable amount of time spent by elders within ECC, information linking contamination of ECC by particles, micro-organisms and exposure of elders continues to be sparse (Almeida-Silva *et al.*, 2014a,b). Thus, societies must provide environments that guaranty the wellbeing of vulnerable groups like the elderly.

The older population is growing faster than the total population in practically all regions of the world – and the difference in growth rates is increasing (United Nations UN, 2012). Since 1996 until 2008 the number of adults aged > 65 years increased 31% (from 380 million to 500 million). According to the United Nations UN (2013) the percentage of total population aged 60 years or over in the world was 11% for the year 2010 and is estimated to be 18% for 2050. Although indoor concentration and number of carcinogenic air pollutants has been decreasing since the 1950s (Weschler, 2009), all of the previously evidences, plus the changes on life-style and the fact that people spend a large part of their life inside indoor environments have promoted an increase on exposure to indoor air pollutants (Byčėnkiėnė *et al.*, 2009; Zhao *et al.*, 2009; Dales *et al.*, 2008; Leech *et al.*, 2002; Klepeis *et al.*, 2001). Consequently, we are witnessing an intensification of studies developed by the scientific community concerning Indoor Air Quality (IAQ) and its effects upon health (Canha *et al.*, 2012a,b; Franck *et al.*, 2011; World Health Organization WHO, 2010; Saliba *et al.*, 2009; Fraga *et al.*, 2008; Fromme *et al.*, 2007; Kosonen and Tan, 2004; Lee *et al.*, 2002; Allen and Miguel, 1995). Indoor air pollution is caused by a combination of several factors: hazardous substances that are emitted from the outdoors, buildings, construction materials, furnishings, equipment, inadequate ventilation, indoor human activities, etc. (Almeida-Silva *et al.*, 2015; Canha *et al.*, 2013; Viegas *et al.*, 2010; Weschler, 2009). Physical factors such as air temperature, air velocity and relative humidity are usually used as indicators of thermal comfort, in IAQ studies. The main chemical and biological parameters used to characterize the IAQ are carbon monoxide (CO) and dioxide (CO₂), the volatile organic compounds (VOC), the formaldehyde (H₂CO), the ozone (O₃), the particulate matter (PM), fungi and bacteria. Several studies positively correlated indoor exposure to microorganisms and microbial components with adverse health effects including headache and respiratory symptoms (Douwes *et al.*, 2003). Considering specifically fungi, their spores are complex agents that may contain multiple hazardous components. Health hazards may differ across species because fungi may produce different allergens and mycotoxins. Moreover, some species also infect humans (Eduard and Halstensen, 2009). Most infections occur in immunocompromised hosts or as a secondary infection, following inhalation of fungal spores or the toxins produced by them (Srikanth *et al.*, 2008). It is known that some people are sensitive to molds and exhibit symptoms such as dry nose, wheezing, and red or itchy eyes or skin when exposed to molds. Severe reactions have also been observed among workers exposed to large amounts of molds in occupational settings including fever and shortness of breath. Exposure to mold or dampness may also lead to development of asthma in some individuals (Centers for Disease Control and Prevention CDC, 2017).

Methodology

In order to identify the scientific publications to be included in this review and analysis, three search engines were used: Web of Science (WoS), Scopus, and Online Knowledge Library (b-on). This strategy allowed to access to the largest number of existing publications under this topic. These search engines were selected due to its interdisciplinary nature, in order to cover several disciplines – from mycology to environmental science.

The search methodology was developed under three steps.

First Step

The follow keywords were selected and search in all selected search engines:

- A. "elderly" + "indoor" + "fung*".
- B. "old*" + "indoor" + "fung*".
- C. "old*" + "indoor air" + "fung*".

Second Step

After the first approach a list of inclusion and exclusion criteria was created, in order to do a deep and refined selection of the retrieved publications. Inclusive criteria: publications that studied indoor environments related to elderly people; publications in English and Portuguese. Exclusive criteria: publications before the year 2000; publications in duplicate; the follow keywords – “child*”, “infant*” and “work”. **Table 1** presents the number of publications under the study in first and second methodological steps.

Third Step

A database with all selected articles was elaborated. During this process all duplicate publications were erased, as well as publications that didn't present any quantitative or qualitative data regarding fungi concentrations in elderly homes. The studies included in this integrative review were selected based on their content. In terms of content, each publication selected for this literature review included results based on empirical data on the relation between fungi concentrations assessed indoors and elderly or old people. Considering the purpose of this study, the possible influence of sociodemographic variables was not considered in this chapter, since it was considered irrelevant.

At the end, 11 publications (**Table 2**) were compiled to be discussed in the next sub-article.

Results and Discussion

Table 2 summarizes the selected publications after the application of the three methodological steps described previously.

The temporal distribution of the 11 publications identified according to the stated criteria was not uniformed. A total of 9% covered the period between 2005 and 2010; 27% represented the period between 2010 and 2015; 64% were from the period between 2015 and 2019. The largest proportion of studies identified in recent years, or in other words since 2015, may be due to the fact that scientific studies about indoor air pollutants in elderly care centers only effectively began in the second half of the 20th century, with scientific production on this theme intensifying from this period onwards.

The selected publications are from Europe (73%) and Asia (27%). **Fig. 1** represents the general characterization of the selected publications according to the country in study. It is possible to observe that Portugal shows the highest percentage (55%) of developed works on the studied field, followed by Asiatic Continent (Iran, Korea and China). This shows a Portuguese great concern about this topic and goes in line with the European society' evolution: (1) in 2014 the Portuguese ageing rate was higher than the European average, with 21% of the population aged 65 or over ([Eurostat, 2014](#)); (2) according to Eurostat, Portugal will have the oldest European

Table 1 Number of publications identified according to each keywords' group, search engine and inclusion and exclusion criteria

Keywords	A		B		C	
	1	2	1	2	1	2
Methodological Step	1	2	1	2	1	2
WoS	46	17	313 ^a	–	212	19
Scopus	15	9	111	14	57	9
b-On	22	11	96	15	47	10

^aDue to the big amount of generated data and the heterogeneity of the results this keywords' group for WoS was rejected.

Table 2 Selected publications after the three methodological steps

Title	Year	Ref.
Airborne microbiological characteristics in public buildings of Korea	2007	(Kim and Kim, 2007)
Biological air contamination in elderly care centers	2014	(Aguilar <i>et al.</i> , 2014)
Fungal Contamination Assessment in Portuguese Elderly Care Centers	2014	(Viegas <i>et al.</i> , 2014)
Indoor air quality and thermal comfort in elderly care centers	2015	(Mendes <i>et al.</i> , 2015)
Indoor and outdoor exposure to ultrafine, fine and microbiologically derived particulate matter related to cardiovascular and respiratory effects in a panel of elderly urban citizens	2015	(Karottki <i>et al.</i> , 2015)
“Avaliação da qualidade do ar interior em lares de idosos, 2013–2014: projeto GERIA” (Portuguese)	2016	(Cano <i>et al.</i> , 2016)
The impact of indoor air quality and contaminants on respiratory health of older people living in long-term care residences in Porto	2016	(Mendes <i>et al.</i> , 2016)
Airborne fungal diversity inside a nursing home in Edirne, Turkey	2017	(Yilmaz <i>et al.</i> , 2017)
Bioaerosol exposure and circulating biomarkers in a panel of elderly subjects and healthy young adults	2017	(Faridi <i>et al.</i> , 2017)
Indoor environmental conditions in urban and rural homes with older people during heating season: a case in cold region, China	2018	(Fan <i>et al.</i> , 2018)
“Qualidade do ar interior em ambiente geriátrico no Nordeste de Portugal” (Portuguese)	2018	(Madacussengua <i>et al.</i> , 2019)

Note: n/d: Not described.

population in 2050, with almost 50% of the population with more than 55 years old. The justification is given by a historical drop in fertility rates, increased average life expectancy and, in some cases, migration patterns (Eurostat, 2019) (see Figure SI 1).

Regarding the methodology of each study it was possible to observe (Table 3) that 63% ($n = 7$) of the selected works used impaction as sampling method, either using the Merck Air Sampler MAS-100 ($n = 4$), the Six-stage cascade impactor (Andersen, Model 10–800) ($n = 1$), the Merck Millipore M Air T ($n = 1$), or the Surface Air System air sampler ($n = 1$) (Table 2). Of those, 5 used malt extract agar (MEA) (two with chloramphenicol added) and 2 Rose-Bengal Chloramphenicol Agar (RBCA). Faridi *et al.* (2017) used the QuickTake® 30 as air sampling device, with a spore trap cassette system, and Sabouraud Dextrose Agar (SDA) supplemented with chloramphenicol as culture medium. Other two studies used a different methodology, based on passive methods: adherent material applied in floor surfaces (Fan *et al.*, 2018); and Electrostatic Dust Cloths (Karottki *et al.*, 2015) using Dichloran Glycerol Agar (DG-18) as culture medium. The applied methodologies regarding temperature and incubation time are not equal through the selected works. For the impaction-based sampling studies, three (Madacussengua *et al.*, 2019; Kim and Kim, 2007; Aguilar *et al.*, 2014) describe similar conditions, with incubation periods from 3 to 5 days in a temperature between 20–25°C. A slight difference could be observed in Cano *et al.* (2016) and Fan *et al.* (2018) with a duration and temperature of incubation around 4–5 days and 25°C, respectively. The other studies, Yilmaz *et al.* (2017), Faridi *et al.* (2017), Karottki *et al.* (2015) and Viegas *et al.* (2014), applied more incubation time for its samples: 5–7 days, and incubation temperatures between 25°C and 29°C. Mendes *et al.* (2015) only presented the temperature of incubation, 25°C.

Although the number of publications is scarce, it is interesting to notice the small divergence of reported results across Europe and Asia: median concentrations (considering all studies) were 350 CFU m⁻³ and 406 CFU m⁻³ respectively, and the most frequently found genera were *Cladosporium* sp., *Penicillium* sp. and *Aspergillus* sp. regardless the region. Knowing that weather

conditions and geography-related vegetation (Jędryczka, 2014; Núñez *et al.*, 2016) are the most accountable factors contributing to airborne fungi diversity, a wider heterogeneity in the results was expected.

Overall, the main findings reported in these publications were:

- (1) Fungi species found in indoor air were similar to the ones found outdoor;
- (2) *Penicillium sp.*, *Aspergillus sp.* and *Cladosporium sp.* were the dominant genera of fungi both indoor and outdoor;
- (3) Levels of fungi indoor were weakly but significantly correlated with the levels of PM_{2.5};
- (4) Median concentration levels of indoor fungi exceed the median outdoor levels during winter season;
- (5) Fungi median indoor concentrations were slightly above references in winter season, and peak values in both seasons (winter and summer) were concerning;
- (6) Significant positive correlations were found between temperature and *Aspergillus sp.*, *Cladosporium sp.* and *Alternaria sp.* levels;
- (7) Correlation between circulating biomarkers, especially IL-6 and white blood cells counts, and fungal aerosols exposure among elderly subjects was found;
- (8) Fungi levels in rural houses were higher than in urban houses.

No Health Authority or equivalent organization has already set specific limits for indoor air pollutants' levels regarding environments harboring particular groups of individuals, as children, the elderly, patients, and other immunologically vulnerable individuals. In addition, for fungi, the only existing regulation for indoor levels is specifically set for indoor environments as a measure of good indoor air quality, yet the values vary greatly between countries/entities. For instance: the European Confederation Commission recommends levels of fungi under 2000 CFU m⁻³; the World Health Organization (World Health Organization WHO, 2009), under 500 CFU m⁻³; the American Industrial Hygiene Association (AIHA) under 1000 CFU m⁻³ (EL-Morsy, 2006); the Turkish Standards Institute under 1000 CFU m⁻³ [TS 12281/Nisan 1997] (EL-Morsy, 2006); the Portuguese government sets the limit of indoor air fungi level at the level of concomitant outdoor air fungi level (Ordinance no 353-A/2013).

The levels of fungi found for elderly care centers varied between 5 CFU m⁻³ and 1343 CFU m⁻³ among the studies in review. Depending on the location, these levels could or not be acceptable. If the indoor concentrations of airborne fungi are higher than the outdoor concentration, the presence of indoor generative sources may be suspected. Nevertheless, from a health perspective the risk that fungi exposure poses is much more related to the susceptibility of the individuals rather than to general limits. As observed in one of the publications a correlation between circulating biomarkers of inflammation – IL-6 and white blood cells count – and fungi exposure could be established for a population of older people. Among older adults, asthma-related hospitalizations have already been associated with the presence of mold in the home environment. (Hsu *et al.*, 2018). These data are suggestive that much more studies are needed to assess the influence of fungi in indoor air and older-people's health.

Conclusion

The growing number of aged populations is a consequence, among others, of the better health conditions that medical progress has enabled. These populations, despite their longevity, may present new challenges as their immune system, resistance, past diseases, and overall frailty may predispose them differently to otherwise non-threatening substances and contaminants. This still growing new reality coupled with changes in lifestyles and environment makes it a priority to fully assess the risk that indoor air contaminants exposure poses to these populations. Establishing safe exposure limits specifically considering these populations needs would result in improved health and quality of life, and a significant reduction in costs with healthcare.

Integrating Fungi in the Drinking Water Regulation and in Guidelines for Materials in Contact With Drinking Water. Is there Room for Change?

Monika Novak Babič, University of Ljubljana, Ljubljana, Slovenia

Introduction

Water is one of the essential natural resources supporting life on Earth. In times of rapid changes in the atmosphere, and increasing global warming, humanity is facing the ongoing environmental crisis. This can be seen by melting glaciers, long periods of drought and on the other side severe weather events, like hurricanes and floods ([Handmer et al., 2012](#)). Meanwhile, the urban environment is expanding in many areas, and affecting surface and underground water sources due to the anthropogenic factors, such as construction work, water flow remediation and pollution ([Cheremisinoff, 1997](#)). Care for safe drinking water becomes now more than ever, one of the humanity's main present and future goals ([Novak Babič et al., 2017](#)). Free access to safe drinking water must be ensured for everyone, as stated by the United Nations Human Rights Council in the Resolution 64/292 ([UN, 2010](#)). Yet, due to the above listed natural and anthropogenic factors, not every fresh water is safe for use in terms of being free of chemicals and microorganisms affecting health ([WHO, 2011](#)). Daily delivery of fresh and safe drinking water is still a challenge in many countries worldwide. World Health Organization (WHO) regularly updates its guidelines with recommendations on methods for water cleaning, disinfection and transport, together with the most problematic chemical- and microbiological agents affecting human health ([WHO, 2011](#)). The final decision on the hazardous agents, included in directives, and the application of water cleaning methods is responsibility of each Member-state and national team, who possess the on-the-field situation knowledge, regarding the water chemical and microbiological suitability ([EEC, 1998](#)). Although many microorganisms, particularly the ones associated with gastro-intestinal illnesses, are already part of the regular monitoring, fungi remain excluded. However, their presence in water is known for a long time. It is frequently associated to "moldy" odor, and to changes in taste and color of water ([Department for Environment, Food & Rural Affairs, 2011](#); [Novak Babič et al., 2017, 2018](#)). Also fungi as part of microbial biofilms have been recognized in different lines of industry using tap water for their operations, often causing clogging of small-diameter pipes, filters and grids ([Douterelo et al., 2016](#); [Liu et al., 2017](#)). Species of the genera *Acremonium*, *Alternaria*, *Aspergillus*, *Cladosporium*, *Fusarium*, *Penicillium*, *Stachybotrys* and *Trichoderma* were commonly related to biodegradation of materials used for water transport, either metal or concrete ([Andersen et al., 2011](#); [Hurtado-McCormick et al., 2016](#)). Yet, the choice of used material in water producing companies has no unified legislative approach in terms of microbiological parameters and depends on in-country authorities and industrial financial budget ([4MS, 2011](#)). However, building materials in contact with drinking water have a significant effect on colonization and later proliferation of fungi, establishment of biofilms and production of fungal secondary metabolites ([Department for Environment, Food & Rural Affairs, 2011](#); [Novak Babič et al., 2017](#)). Fungal particles and their metabolites may affect human health when released with drinking water via direct contact or aerosolisation. Health implications due to fungal presence and possible proliferation within drinking water distribution systems already raised concerns in the past ([Novak Babič et al., 2017](#)). In times of prolonged human life span and raising occurrence of antimicrobial resistance, fungi became studied as potential infectious agents with occasional, but expanding anti-mycotic resistance ([Chiller, 2016](#)). The latter is particularly worrisome for the genera *Aspergillus*, *Candida* and *Fusarium*, due to their opportunistic nature, speed of resistance emergence and the ubiquitous presence in nature ([Rivero-Menendez et al., 2016](#); [De Hoog et al., 2019](#)).

In terms of broadening the knowledge on fungi in drinking water the present article enlightens the current legislative background and the main future concerns regarding the inclusion of fungal parameters in water directives. Additionally, we present the European on-the-field situation on fungi in drinking water, pointing out the most common genera with the major effect on materials in drinking water transport network and effect on human health.

Why are Fungi in Drinking Water a Present and a Future Legislation Problem?

Regulation and Legislation

Drinking water is a necessity and through history humanity learned that poor water quality significantly affects health and may be even deadly ([Gray, 2014](#)). To date, the World Health Organization (WHO) recommended monitoring of many different species of protozoa, bacteria and viruses ([WHO, 2011](#)). Protozoa include *Acanthamoeba* spp., *Cryptosporidium hominis*, *C. parvum*, *Cyclospora cayatanensis*, *Entamoeba histolytica*, *Giardia intestinalis*, and *Naegleria fowleri*. Drinking water should be monitored for bacterial species *Burkholderia pseudomallei*, *Campylobacter jejuni*, *C. coli*, *Escherichia coli* and enterohaemorrhagic *E. coli*, *Francisella tularensis*, *Legionella* spp., *Leptospira* spp., *Mycobacteria* (nontuberculous), *Salmonella typhi* and other salmonellae, *Shigella* spp., *Vibrio cholerae*, and cyanobacteria. Also, Coliphages, Adenoviruses, Astroviruses, Enteroviruses, Hepatitis A, Hepatitis E, Noroviruses, Rotaviruses,

and Sapoviruses are in the WHO recommendation list. Many more are on the “suggested” list (WHO, 2011). Microbial species selected for monitoring by each country may vary due to the geographical positions, related climate factors (e.g., temperature and relative humidity) and the potential for the presence of specific taxa of microorganisms in drinking water (Percival *et al.*, 2014). However, there is a void in the WHO recommendation for algae and fungi. Recommendations only state that any algae causing bad taste or odor, and toxins producers should be absent, while “Fungi causing bad taste and odor should be minimized” (WHO, 2011). Therefore, European Member-states and other countries do not list any specific fungal taxa among parameters for water monitoring (EEC, 1998; US EPA, 2016). There is nonetheless a modest fungal contribution within the heterotrophies plate count, which indicates changes in microbial concentration, like ingress or regrowth in water distribution systems (WHO, 2003), but with no specific regulatory value since the compliance is defined as “no abnormal change” (Novak Babič *et al.*, 2017). Despite this framework of regulatory void for fungi in drinking water, a few countries decided, nonetheless, to include fungi as a parameter for drinking water quality. Within the European Union (EU) the Czech Republic requires microscopic observation of all microorganisms in concentrated drinking water samples taken at consumers’ taps with a parametric value of 50 individuals per milliliter, including filaments and spores (Ministry of Health, 2004). Hungary uses similar approach, with the difference of parametric values being set separately for each group of organisms. The value for fungi at end-point users is 0 individuals per 1 l (Ministry of Health, 2001). The only legislation on fungi in drinking water to date requiring the direct detection of fungi by culture dependent method is the Swedish legislation. Their parametric value for “microfungi” (including molds and yeasts) is set to 100 colony forming units CFU per 100 mL (NFA, 2001). Many reasons contribute to the global legislative void of fungal parameters in drinking water, the main ones being the lack of knowledge on fungal groups in water and the lack of uniform approach for their detection and identification.

The Lack of Knowledge on the “Core Fungal Species” Connected to the General Water Quality and/or Human Diseases

The first reason could be the lack of knowledge on a potential common group of fungal taxa (i.e., “core species”) connected to either general water quality and/or human diseases. Conceptually speaking, fungal water biota is highly dependent on natural features, like the use of main raw water sources, pollution and climate, thus non-core fungal contaminants can drastically vary among different countries (Novak Babič *et al.*, 2017, 2018). For these reasons, common fungi that may represent an equivalent criterion for global water quality, including effects on taste, odor, material degradation and mycotoxin production may be quite difficult (Novak Babič *et al.*, 2017).

Similarly was observed for the determination of water-borne fungi causing human diseases. Contrary to bacteria and viruses, water-borne fungi more likely pose a long-term health hazard via the production of secondary metabolites than the onset of an immediate disease (Department for Environment, Food & Rural Affairs, 2011; Novak Babič *et al.*, 2017). In cases of disease development, fungal infections usually have a long incubation period and the primary source of infection can become problematic to trace (De Hoog *et al.*, 2019). Also, more than one fungal genus may cause infections, depending mainly on the state of the host’s immune system. The vast majority of patients suffering from an invasive fungal infection frequently suffer from an underlying disorder, such as diabetes mellitus, cystic fibrosis, cancer, AIDS or they suffered severe burns or underwent an organ transplantation (De Hoog *et al.*, 2019). Infections caused by fungi are thus primarily limited to certain groups of immunocompromised people and are usually not highly contagious among humans as in the case of some bacteria and viruses (De Hoog *et al.*, 2019). Drinking water was thus to date rarely designated as a direct source of fungal infections in regular circumstances.

Setting Equivalent Methods for Enumeration or Cultivation of Fungi

The second reason may occur when setting the equivalent methods for enumeration or cultivation of fungi. The main problem is high diversity of fungal growth forms (Novak Babič *et al.*, 2017). Proliferation does not occur exclusively by unicellular particles displacement, but instead fungi may germinate from different kind of spores, pieces of hyphae, yeasts or meristematic clumps (De Hoog *et al.*, 2019). Due to these differences microscopic enumeration often shows discrepancies in comparison to the growth on solid media (Novak Babič *et al.*, 2017). Also, not all fungi related to water quality or diseases are able to grow on only one selected medium (usually Sabouraud or potato-dextrose agar). In future more cultivation media should be used to broaden the knowledge on water-borne fungi, which may raise costs and prolong identification (Gonçalves *et al.*, 2006; Novak Babič *et al.*, 2017) and more common approaches should be employed.

Correct and Uniform Identification of Fungi

Another problem is fungal identification to the species level. Microscopic observations are rarely correct (De Hoog *et al.*, 2019). Even after visible growth on a common cultivation media, not all fungi form distinctive macro- and micro-morphological features. Some genera may thus not be identified correctly in laboratories equipped with only the basic equipment (Novak Babič *et al.*, 2017). The molecular approach is a good alternative to microscope identification, but sometimes even the internal transcribed spacer (ITS) used as a general fungal barcode fails to identify fungi to the genus or species level, prolonging identification time and increasing costs (Irinzi *et al.*, 2015). Lastly, correct and uniform identification of fungi may represent an issue for laboratories lacking people trained in mycology, since fungal taxonomy is currently facing a huge restructuring, known

under the term “one fungus – one name”, frequently resulting in old names being recently replaced or combined based on recognition of both sexual and asexual forms (Taylor, 2011).

Exploring Fungi in Water Distribution Systems

Fungi may not be the usual parameter related to water quality monitoring, but they were nevertheless studied by many European research groups during the last 30 years (Novak Babič *et al.*, 2017). For this chapter we included and analyzed reports on water-related fungi from 19 European countries: Austria, Belgium, Finland, France, Germany, Greece, Hungary, Italy, Norway, Poland, Portugal, Serbia, Slovakia, Slovenia, Spain, Sweden, The Netherlands, Ukraine and United Kingdom. These studies included raw water sources (either groundwater or surface water) used for preparation of potable water, as well as finished drinking water at consumers' endpoint (Novak Babič *et al.*, 2017). Although the factors influencing fungal presence vary amongst countries, we looked for the fungi commonly occurring in water, regardless of geographically bound disparities: the “core-species”.

“Core Species” and Diversity of Fungal Communities Depend on the Main Raw Water Source

Geographic location and the climate of countries have an important influence on the fungal diversity. The main factors influencing the occurrence of fungi in raw water are temperature, humidity, rainfall rate, presence of different plants (Wurzbacher *et al.*, 2011), and geological features determining the position of the aquifers. Geological features may not vary only between the countries, but also within a country. In some cases, countries have only one type of water source, whilst others may have access to both surface water and groundwater, or even to mixtures of both, as regularly seen in the karst systems (Novak Babič *et al.*, 2017). One of the important factors, observed particularly in large valleys and basins with a high population density (urban environment), is water pollution with organic or inorganic substances (Gray, 2014). Plastics, crude oil and other complex hydrocarbons can be degraded by fungi in the presence of water. These compounds thus represent the ideal scaffold for fungal attachment and proliferation (Steffen *et al.*, 2002). This phenomenon usually affects local areas but plays an important role in cases of natural disasters (e.g., floods, earthquakes, drought, fire), or disasters caused by humans (e.g., oil spills) (Novak Babič *et al.*, 2018). During such disasters, waters are often displaced, and can carry fungal propagules to longer distances. As a consequence, a shift in fungal biota may occur (Novak Babič *et al.*, 2018).

Considering the above-mentioned facts, fungal diversity in the drinking water of European countries often shows locally highly abundant genera or species related to the specifics of the water or country (Novak Babič *et al.*, 2017). Presence of certain locally isolated fungal genera should not be excluded just because they do not fit into the general European picture. Instead, they should be carefully evaluated for each country, especially if the most abundant fungi increase after unexpected events and belong to the opportunistic pathogens.

Despite different geographical locations, geological features, techniques applied on the raw water sources for their cleaning, as well as different fungal cultivation and identification techniques used by different laboratories, some conclusions on fungal water biota of European countries can be summarized. It seems that the location of the raw water source has the most important effect on the presence of fungi in final drinking water (Novak Babič *et al.*, 2017, 2018). Countries using surface water as the main water source more frequently reported the presence of soil- and plant-degrading fungi in final drinking water, such as *Penicillium*, *Aspergillus*, *Botrytis*, *Geotrichum*, *Mucor*, *Rhodotorula*, *Scopulariopsis* and *Trichoderma* (Pereira *et al.*, 2010; Novak Babič *et al.*, 2017). These genera were reported from 20% to 26% countries, with *Penicillium* being most frequently detected (in 26% of countries).

Conversely, countries with groundwater related tap water frequently isolated the genera *Alternaria*, *Aspergillus*, *Phialophora*, *Cyphellophora*, *Exophiala* and *Paecilomyces* (Göttlich *et al.*, 2002; Heinrichs *et al.*, 2013; Biedunkiewicz *et al.*, 2014). The percentage of countries reporting their presence ranged from 26% to 47%, with *Alternaria* and *Aspergillus* being the most abundant (47%) (Novak Babič *et al.*, 2017). Melanised, black fungi with thick cell walls and fungi with small diameter of spores were generally more likely present in groundwater (Novak Babič *et al.*, 2017). The reason remains unknown, but it could be hypothesized as related to the low porosity of rocks, presence of certain ions, like calcium and magnesium, and low organic material, promoting growth of oligotrophic species (Novak Babič *et al.*, 2017).

The above listed fungi add to differences in quality of captured raw water and may also significantly affect the final drinking water quality.

The Most Common Fungi Isolated From European End-Point Drinking Water

Raw water sources with diverse fungal biota are used for production of drinking water. Depending on the general quality of the raw water, complying with the regulating Directive, several mechanic-chemical steps may be applied on the captured raw water (EEC, 1998; WHO, 2011). Since there is no legislation requiring monitoring of fungi in natural water, consequently there is little data about the influence of certain water cleaning steps on the removal of fungi from natural water sources (Novak Babič *et al.*, 2017). However, in vitro studies conducted with single fungal strains have reported removal between 8% and 90% of fungi using mechanical treatments (e.g., sand filtration, coagulation, flocculation), and inactivation of 97%–99% of fungi with free chlorine

concentration reaching 2 ppm (Department for Environment, Food & Rural Affairs, 2011; Pereira *et al.*, 2013). Despite water cleaning procedures and general good quality of drinking water complying with the Directive's parameters, fungi often remain present and reach end-point consumers. Species reported as a cross-section of fungi from surface water, groundwater and drinking water from European countries are *Acremonium* spp., *Acrostalagmus luteoalbus*, *Alternaria alternata*, *Aspergillus clavatus*, *A. flavus*, *A. fumigatus*, *A. niger*, *A. terreus*, *A. ustus*, *A. versicolor*, *Aureobasidium* spp., *Beauveria bassiana*, *Cadophora malorum*, *Cephalosporium* spp., *Cladosporium cladosporioides*, *C. halotolerans*, *C. herbarum*, *Coniochaeta hoffmannii*, *Didymella molleriana*, *Epicoccum nigrum*, *Fusarium oxysporum*, *F. solani*, *Geotrichum* spp., *Gliocladium* spp., *Isaria farinosa*, *Lecanicillium lecanii*, *Leptosphaeria* spp., *Paecilomyces variotii*, *Penicillium brevicompactum*, *P. chrysogenum*, *P. corylophilum*, *P. glabrum*, *P. spinulosum*, *Phialophora fastigiata*, *Phoma herbarum*, *Ph. leveillei*, *Pilidium concavum*, *Purpureocillium lilacinum*, *Sarocladium strictum*, *Stachybotrys chartarum*, *Trichoderma harzianum*, *T. viride*, *Rhodotorula* spp., and *Mucor* spp. (Department for Environment, Food & Rural Affairs, 2011; Novak Babič *et al.*, 2017). While most of the listed fungi occurred in a low number of countries, 25%–50% of EU countries regularly reported presence of the genera *Rhodotorula* (25%), *Alternaria*, *Mucor* (both 32%), *Paecilomyces* (37%), *Phoma*, and *Aureobasidium* (both 42%) in all three water types (Novak Babič *et al.*, 2017). The most commonly detected or isolated fungi belong to the genera *Trichoderma*, *Fusarium*, *Acremonium* (all 63% countries), *Aspergillus* (68%), *Penicillium* (74%) and *Cladosporium* (84%) (Novak Babič *et al.*, 2017). Presence of other yeasts beside *Rhodotorula* was not determined in detail, either because they were not included in the studies or they were overlooked due to used cultivation techniques, usually promoting growth of filamentous fungi (Novak Babič *et al.*, 2017).

Fungal genera reported from drinking water from more than 50% of European countries, despite of the origin of raw water source, may be considered as a part of the core fungal biota. As widespread, they very likely influence also the biofilm formation and biodegradation of materials in contact with drinking water. Additionally, they should not be overlooked when discussing the possible effect on health among European population.

Fungal Effect on Used Building Materials in Water Distribution Networks

After cleaning procedures freshly produced drinking water is usually retained in reservoirs before it is distributed to consumers. The networks of pipes and reservoirs are built of various materials and alloys (Nlzh and Nijz, 2016). The most commonly used materials for water transport are concrete, mortar, gypsum, ceramic tiles, plastic materials (e.g., polyethylene (PE) and its derivatives – PEX, GFRP, and rubber), and different metal alloys (e.g., copper and its alloys; Cu-Zn, Cu-Zn-As, Cu-Zn-Pb, Cu-Zn-Pb-As, etc.) (4MS, 2011). Each of the used materials reacts differently with water and thus their long-life stability depends greatly on the chemical features of water, and disinfectants used, particularly chlorine, and its by-products (e.g., chloramines) (Gray, 2014). For now, the European Union (EU) does not have a uniform approach for quality and adequacy for materials and their products in contact with drinking water. However, four member states (4MS; France, Germany, The Netherlands and the United Kingdom) issued standardized procedures for the approval of building materials and final products for water networks (4MS, 2011; Nlzh and Nijz, 2016). The document sets also standard procedures in order to determine possible corrosion and growth promotion of total coliforms at 37°C and total microbial count at 22°C, but does not directly include fungi (Nlzh and Nijz, 2016). However, studies conducted during the last two decades frequently linked the occurrence of fungi in water networks to the choice of building materials. Materials more susceptible to biodegradation may result in elevated growth of biofilms, affecting the stability of residual disinfection, slowing water flow and weakening shear forces (Department for Environment, Food & Rural Affairs, 2011).

Colonization and Biodegradation of Materials in Contact With Drinking Water Induced by Water-Related Fungi

Most widely used building materials in water industry are concrete, metal and plastic materials. Plastic in particular constitutes almost 90% of materials used to build pipes in new constructions (Andrady and Neal, 2009; Bertron, 2014). The number of microorganisms in water significantly increases in certain parts of the supply systems which promote biofilm formation (Fig. 1).

Although biofilm formation occurs independently of the hydrophobicity or hydrophilicity of the material, the available reports show higher presence of fungi and bacteria on rough surfaces and those made of iron or steel in comparison to plastic materials (Doggett, 2000; Grabińska-Łoniewska *et al.*, 2007). The main reason is probably the reaction of metals with residual chlorine in water, lowering its harmful effect on microbial biofilms (Le Chevallier, 1999).

Surface characteristics and material composition exerts a strong selective pressure on fungal biodiversity. The most used building material for large water retention centers, storage tanks, and main pipes for water transport is rough concrete (Bertron, 2014). After prolonged time of being in direct contact with water, its relative humidity raises above 90%, representing ideal conditions for growth of water-borne, hydrophilic fungi (WHO, 2009). Concrete is often colonised by the filamentous genera *Bjerkandera*, *Sporothrix*, *Chaetomium*, and *Penicillium*, while yeast biota on concrete is constituted mainly of *Candida*, *Debaryomyces*, *Kluyveromyces*, *Meyerozyma* and *Rhodotorula* species (Andersen *et al.*, 2011; Hurtado-McCormick *et al.*, 2016). In addition, species *Aspergillus fumigatus*, *A. melleus*, *A. niger*, *A. versicolor*, *A. ochraceus*, *Mucor racemosus* and *M. spinosus* colonize concrete combined with different adhesives (Andersen *et al.*, 2011). Finishing materials, such as plaster, gypsum or fiberglass are usually colonised by *Acremonium*, *Cladosporium*, *Penicillium*, *Stachybotrys*, *Ulocladium*, and *Phoma* (Andersen *et al.*, 2011; Fig. 2). Depending on the core species, fungal growth and metabolism may affect concrete in two ways: (i) local scaling due to the production of organic acids, as

Fig. 1 The presence of fungi on various materials in contact with water, in untreated water and in drinking water. A: Fungal colonies on the surface of the concrete coating in water storage facility (indicated by the red arrow); B: *Aureobasidium melanogenum* (black colonies) and *Aspergillus* sp. (green colonies) isolated from 1 L of untreated water on DRBC agar; C: Visible biofilm on the metal and rubber parts of the pipe (marked with red arrows); D: Sample taken from the inside of the rubber tube after incubation on the SABG agar with the addition of penicillin and streptomycin, visible bacteria *Sphingomonas* sp. (yellow colonies) and black yeast *Exophiala* sp.; E: DRBC agar with visible *A. melanogenum* (large, pink colonies), *Rhodotorula mucilaginosa* (red yeast), *Bisifusarium dimerum* (white colonies), and *Aspergillus fumigatus* (green colony) isolated from 1 L of chlorine-treated drinking water sampled from the pipe at end-point user.

shown for *Aspergillus*, *Penicillium* and *Stachybotrys* (Andersen *et al.*, 2011; Luo *et al.*, 2018); (ii) dissolution of $\text{Ca}(\text{OH})_2$, and precipitation of calcite on the surface of fungal hyphae as confirmed for *Trichoderma reesei* and *Candida tropicalis*. These changes are well known under the term “self-healing concrete” (Luo *et al.*, 2018; Menon *et al.*, 2019).

While concrete covers large areas due to its use for water retention, metal alloys (e.g., different types of brass and stainless steel) represent smaller percentage of materials in contact with water. They are usually used as a part of ductile pipes (ductile iron), for water pipes with small diameter, and for couplings and counters (Hurtado-McCormick *et al.*, 2016). Water-associated fungi damage metal materials locally, causing extensive separation into layers, pitting and intercrystallite corrosion (Semenov *et al.*, 2006). Ductile iron and iron have been colonised and degraded by *Penicillium ochrochloron*, *P. glabrum* and *P. janthinellum* and ubiquitous yeast *Debaryomyces hansenii* (Hurtado-McCormick *et al.*, 2016). Destruction of aluminum and magnesium alloys has been observed for *Aspergillus niger* (Semenov *et al.*, 2006). Also, aluminum and steel wires are commonly colonised by *A. niger*, as well as *A. amstelodami*, *Chaetomium globosum*, *Stachybotrys atra* and various fungi of the genera *Aureobasidium*, *Alternaria* and *Stemphylium* (Semenov *et al.*, 2006). On the contrary, copper wires have been reported as the most resistant to fungal colonization, with genus *Penicillium* being the only one detected (Semenov *et al.*, 2006). *Penicillium* spp., *Aspergillus fumigatus* and *Sarocladium kiliense* are often involved in biocorrosion of multiphase and mild steels (Rovetta *et al.*, 2014; Imo *et al.*, 2018). Additionally, metal parts, like grids at the end of the indoor faucets harbor yeasts like *Candida parapsilosis* and black yeasts *Exophiala* spp. (Zupančič *et al.*, 2016). Although zinc has been known as rarely colonised by fungi, several zinc parts of shower also harbored *Penicillium chrysogenum*, *P. purpurogenum* and *P. lilacinus*, together with yeasts *Debaryomyces hansenii*, *Rhodotorula mucilaginosa*, and *Cryptococcus diffluens* (Hurtado-McCormick *et al.*, 2016).

Fig. 2 Biodegradation of mortar and concrete inside water storage tank occurring under usual water level. A: Cementitious ceiling of water storage tank, affected by biodegradation with visible brown and black colonies (indicated by black circle); B: closer photo of visible fungal colonies with mixed genera on the ceiling. Tape samples of colonies, indicated with red, green and blue colors, were taken for further microscopical analysis; C: biodegradation with several fungi seen as in-deep growth of hyphae and meristematic clumps, mechanically degrading mortar; D: monoculture forming large chains of spores appearing directly from the mortar surface; E: mixed fungal culture with visible chains of dark spores and centrally pale brown conidiophores with 3–6 phialides and slimy heads full of transparent conidia. The latter was identified as *Mucillium theobromae*.

During last decades, plastic materials, such as polyvinyl chloride (PVC) and high or medium density polyethylene (HDPE/MDPE), became widely used in water transportation, particularly in household water networks due to easier cleaning, slower biofilm formation, and consequently lower biodegradation potential in comparison to metal (Semenov *et al.*, 2006; Fish *et al.*, 2016). Petroleum-based plastics, such as polyethylene (PE), poly(ethylene terephthalate) (PET), polystyrenes (PS), polyurethanes (PUs), and polyvinyl chloride (PVC), are highly resistant to microbial biodegradation (Hyde *et al.*, 2019). Plastic pipes also do not react with residual chlorine, as is often the case with metal alloys, and thus provide long-distance quality of transported water (Department for Environment, Food & Rural Affairs, 2011). So called “soft-plastics” like neoprene, nylon, silicones and rubber seals, mainly used for sealing couplings and the end-point pipes, are more prone to fungal colonization (Naismith *et al.*, 2017). Due to roughness they represent a good scaffold for yeasts *Candida* spp., *Cystobasidium sloofiae*, *Meyerozyma guilliermondii*, *Naganishia* spp., *Rhodotorula mucilaginosa* (many of which act as primary colonizers) and black yeast-like fungi *Aureobasidium melanogenum*, *Cladophialophora* spp., *Exophiala* spp., *Phialophora* spp., *Cyphellophora* spp. and *Rhinocladiella similis* (Zupančič *et al.*, 2016; Novak Babič *et al.*, 2017). Additionally, molds of the genera *Phoma*, *Scedosporium*, *Cladosporium* and *Fusarium* can be commonly detected (Hamada and Abe, 2009; Zupančič *et al.*, 2016). Filamentous fungi of the genera *Alternaria*, *Aspergillus*, *Aureobasidium*, *Cephalosporium*, *Fusarium*, *Penicillium*, *Rhizopus*, and *Trichoderma* have been recognized as the main agents of microbiological damaging of the PVCs (Semenov *et al.*, 2006). Compact plastic materials, as plasticized polyvinyl chloride (pPVC) are usually colonised and degraded by filamentous fungi *Alternaria alternata*, *Aspergillus* spp., *Aureobasidium pullulans*, *Bipolaris* spp., *Epicoccum nigrum*, *Paecilomyces lilacinus*, *Penicillium* spp. (Webb *et al.*, 2000; Hyde *et al.*, 2019). Other fungi like *Aspergillus flavus*, *A. niger*, and *Fusarium* spp. degrade polycaprolactone (PCL), *Talaromyces* and *Penicillium* species degrade biopolymeric polyhydroxybutyrate (PHB), and *Aspergillus terreus*, *A. tubingensis*, *Chaetomium globosum*,

Curvularia senegalensis, *Pestalotiopsis microspora*, and *Trichoderma* spp. were reported for degradation of polyurethane (PU), particularly polymers with ether bond, more susceptible to fungal degradation than polyurethanes with ester bonds (Hyde *et al.*, 2019; Semenov *et al.*, 2006). It has been shown that also the use of certain metals like iron and magnesium oxide as additives to plastics can promote the attachment and growth of certain fungi (Semenov *et al.*, 2006), while zinc oxide and titanium oxide diminish it (Semenov *et al.*, 2006). Fungal colonization of plastic materials becomes more problematic with time, due to the release of potentially toxic substances from degraded plastic into drinking water (Semenov *et al.*, 2006).

Fungi from drinking water represent important components of biofilm, containing up to 8.9 CFU cm⁻² of yeasts and 4.0–25.2 CFU cm⁻² of filamentous fungi (Doggett, 2000; Grabińska-Łoniewska *et al.*, 2007). They usually enter the biofilm symbiosis as secondary colonizers, actively producing extracellular polymeric substances, particularly humic acids and aliphatic constituents (Claus *et al.*, 1999). Active growth in hyphal form also enables better bacterial attachment and contributes to biofilm stability (Harding *et al.*, 2009). Fungal biofilms can be fully formed within 48–72 h in experimental systems mimicking real water network conditions (Fish *et al.*, 2016), as shown with yeasts *Candida*, *Saccharomyces*, *Naganishia* (former *Cryptococcus*) and *Aureobasidium*, and molds *Acremonium*, *Aspergillus*, *Penicillium*, *Coriolus*, *Neocosmospora*, and *Trichoderma* (Harding *et al.*, 2009; Kauffmann-Lacroix *et al.*, 2016; Douterelo *et al.*, 2018). Fungal biofilms in water pipes frequently raise concerns in hospital environments due to the possible health effect and in industrial water networks, due to slowing work processes and clogging (Fish *et al.*, 2016). Such investigations most frequently revealed the presence of opportunistic species of the genera *Aspergillus*, *Candida*, *Exophiala*, *Fusarium*, *Malassezia*, *Ochroconis*, *Penicillium*, *Phialophora*, *Phoma* and *Rhinocladiella* (Novak Babič *et al.*, 2017).

Biodeterioration and biodegradation of material occurs with the maturation of formed biofilms starting by chemical and later followed by mechanical degradation. Microorganisms can either mobilize (solubilize) or immobilize (accumulate, precipitate) metals (Dighton and White, 2017). Mobilization occurs via redox processes, hydrolysis, chelation, or methylation. Immobilization includes redox processes, complexation, biosorption and biomineralization (Dighton and White, 2017). Complexation of materials happens due to the local production of high concentrations of chemically aggressive metabolites, such as organic and mineral acids, bases, CO₂, alcohols, and sulfur compounds (Dighton and White, 2017; Hyde *et al.*, 2019). Acid's production is well known for the species *Aspergillus niger*, *A. brasiliensis*, *A. flavus*, *A. terreus* and *A. itaconicus*, commonly producing high concentrations of succinic, itaconic, and L-malic acid (Dighton and White, 2017). Second most frequent producers of acids are species of the genus *Penicillium*, producing succinic, gluconic and (–)-trans-2,3-epoxysuccinic acid (Dighton and White, 2017). Other acid producers, frequently isolated from water, belong to the genera *Fusarium* (succinic acid), *Paecilomyces*, *Talaromyces* (both produce (–)-trans-2,3-epoxysuccinic acid), and zygomycetous *Actinomucor*, *Mucor*, *Cunninghamella*, *Circinella* and *Rhizopus*, producing fumaric acid (Hyde *et al.*, 2019; Dighton and White, 2017). Basidiomycetes isolated from water (e.g., *Stereum hirsutum*) rarely produce acids, but they may produce ethanol as one of the main precursors in the metabolic acid production (Hyde *et al.*, 2019). Effects of chemical dissolution of materials can be noticed as “swampy” odor and taste of drinking water (Department for Environment, Food & Rural Affairs, 2011).

Once materials become weak due to the chemical dissolution, fungi may additionally degrade them by mechanical disruption caused by in-depth growth of hyphae (Bertron, 2014), as was shown for water-related genera *Alternaria*, *Aspergillus*, *Cephalosporium*, *Cladosporium*, *Mucor*, *Penicillium*, *Rhizopus*, and *Trichoderma* (Shinkafi and Haruna, 2013; Luo *et al.*, 2018). Effects of mechanically degraded material (usually predominant on concrete and metals) are visible in a range from a slight change of color to pieces of corroded metal present in water. These effects might not be toxic, but they can be unpleasant for most consumers and should be avoided (WHO, 2011; Department for Environment, Food & Rural Affairs, 2011).

How Big is the Health Risk Due to Fungal Presence in Tap Water for End-Point Users?

Once established, biofilms are hard to remove from water-retention reservoirs and pipe systems (Fish *et al.*, 2016). On the long-term, the phenomenon leads to altered color, taste and odor of water and, additionally, to the production of allergenic and irritating compounds (MVOCs) (Department for Environment, Food & Rural Affairs, 2011; Novak Babič *et al.*, 2017). In cases of people with immune deficiency fungi may also initiate an infection (Novak Babič *et al.*, 2018; De Hoog *et al.*, 2019).

Development of Fungal Disease due to Contaminated Water

Besides drinking, consumers use potable water also for daily activities such as cooking, washing and personal hygiene, where they come in contact with fungi directly via the skin and mucosae while washing, digestive system while drinking, and through the respiratory system by inhaling aqueous aerosols (Novak Babič *et al.*, 2017, 2018). Shower hoses can be colonised by *Aspergillus glaucus*, *Cladosporium* spp., *Exophiala mesophila*, *Fusarium fujikuroi* species complex, *Malassezia restricta*, *Penicillium* spp., and *Schizophyllum commune* (Moat *et al.*, 2016). Some studies linked elevated numbers of fungi in the bathrooms' air and on surfaces with the use of showers (Anaissie *et al.*, 2003). Molds were recovered in 70% of samples and included fungi often responsible for asthma symptoms, hypersensitivity pneumonitis and skin irritation (i.e. *Alternaria*, *Acremonium*, *Aspergillus*, *Cladosporium*, *Fusarium*, *Paecilomyces*, and *Penicillium*) (De Hoog *et al.*, 2019). Water-borne fungi, such as *Acremonium*, *Aspergillus*, *Candida*, *Cladosporium*, *Cryptococcus*, *Exophiala*, *Fusarium*, *Penicillium*, and *Rhodotorula* are often reported from dental unit waterlines, especially after prolonged chemical treatment with chlorine and elimination of dominant bacteria (Porteous *et al.*, 2003; Göksay *et al.*, 2013;

Lisboa *et al.*, 2014; Damasceno *et al.*, 2017). Special attention should be given to dialysis water in hemodialysis units, where melanised water-borne fungi of the genera *Cadophora*, *Cladosporium*, *Cladophialophora*, *Exophiala*, *Phialemonium*, and *Rhinochlamydia* can colonize silicone-based materials for water transport (Figel *et al.*, 2013; Kadaifçiler *et al.*, 2013; Mesquita-Rocha *et al.*, 2013).

In general, water-borne fungi of the genera *Alternaria*, *Aspergillus*, *Aureobasidium*, *Candida*, *Cladosporium*, *Fusarium*, *Malassezia*, *Mucor*, *Penicillium*, *Rhodotorula* and *Trichoderma* are regularly present on skin, oral cavity and gastrointestinal tract mycobionts (Underhill and Iliev, 2014; Damasceno *et al.*, 2017). Moreover, species of genera *Aspergillus*, *Cladosporium* and *Scedosporium* can be found transiently in the respiratory tract of healthy individuals, causing transient immune responses like coughing and irritation (Underhill and Iliev, 2014). The above listed fungal genera are opportunistic pathogens, often reported as causative agents of skin, hair and nails infections, and respiratory diseases, such as allergies, asthma and sinusitis (De Hoog *et al.*, 2019). Serious and life-threatening systemic fungal infections may develop in individuals suffering from autoimmune disorders, cystic fibrosis, long-term hospitalization and impaired immune system due to previous viral or bacterial infection, diabetes, cancer or transplantation (Anaissie *et al.*, 2003; De Hoog *et al.*, 2019). Globally, these groups of patients are mainly at risk to get infected with water-related fungi of the genera *Aspergillus*, *Candida*, *Cryptococcus*, *Fusarium*, *Mucor*, and causative agents of chromoblastomycoses (e.g., *Cladophialophora*, *Exophiala* and *Fonsecaea*) (Bongomin *et al.*, 2017).

While most fungal infections are treated with azole compounds, a sudden increase of azole-resistant strains in recent years causes great concern. In particular, species of the genus *Aspergillus* are the predominant fungi developing resistance to azoles, which is believed to have been triggered by the mass use of azole-containing fungicides in agriculture (Verweij *et al.*, 2009). Crops' protection products are not present only in soil but can be detected also in water, leading to the selective pressure, resulting in propagation of azole-resistant strains (Hollomon, 2017). Such occurrences are higher in surface water, due to direct contact with sewage water collected from crops, as shown for *Candida* spp. (Monopathi *et al.*, 2017). In Netherlands they already confirmed drinking water as the main vector for azole resistant *Aspergillus fumigatus* in infected patients (Warris *et al.*, 2003). These incidences put tap water under scrutiny when suspecting infections with azole-resistant fungi (Monopathi *et al.*, 2017).

Indirect Health Effects Due to the Secretion of Fungal Secondary Metabolites

Another way for fungi to affect health is the production of VOCs and mycotoxins. Fungi, in particular the presence of the genera *Acremonium*, *Aspergillus*, *Penicillium* and *Phialophora*, affect the odor and taste of drinking water due to the production of geosmine (Department for Environment, Food & Rural Affairs, 2011). Other VOCs that can be frequently detected in tap water systems are phenols, alkanes, alkenes, and monoterpenes, some of which are genotoxic (Hurtado-McCormick *et al.*, 2016) or they may cause intoxications (Kauffmann-Lacroix *et al.*, 2016). Particularly macrocyclic trichothecenes, alkaloids, fumonisin B, and ochratoxin A are neurotoxic upon ingestion or inhalation of aerosols (French *et al.*, 2019). Recent research of data from 923 Counties of the United States of America (USA) found a significant correlation between mortality due to motor neurone diseases (MND) and the prevalence of well water use. For the first time there was speculation about prolonged exposure (e.g., via drinking, inhaling) to mycotoxigenic fungi from well water as the possible cause of sporadic amyotrophic lateral sclerosis (ALS) as the most common MND disease in adults (French *et al.*, 2019). Similarly, studies on ALS conducted in Spain (Alonso *et al.*, 2015, 2017) and Italy suspected drinking water and fungi to be the possible cause of sporadic ALS (Vinceti *et al.*, 2010). The mycotoxigenic hazard is presumably lower in chlorinated water in comparison to unchlorinated water (Mata *et al.*, 2015), due to the complete degradation of aflatoxin B1, occurring 30 min after exposure to chlorine (McKenzie *et al.*, 1997). However, the same effect was not recorded for aflatoxins B2 and G2, even after several days of water chlorination (McKenzie *et al.*, 1997; Mata *et al.*, 2015). Their study on the presence of mycotoxins in bottled water and tap water confirmed the instability of mycotoxins in tap water treated with chlorine, while in bottled water aflatoxin B2 was the most frequently detected mycotoxin, followed by aflatoxin B1, aflatoxin G1 and ochratoxin A. In all cases levels were below the European maximum limits for mycotoxins in food products (Mata *et al.*, 2015). Ubiquitous fungi *Cladosporium*, *Penicillium* and *Fusarium* were isolated in most of those samples, while other mycotoxin producing genera, *Aspergillus*, *Rhizopus*, *Trichoderma*, *Acremonium*, *Beauveria*, *Mucor*, *Paraconiothyrium*, *Cadophora*, and *Cunninghamella*, were isolated only sporadically (Mata *et al.*, 2015). Although mycotoxins were not frequently present in chlorinated drinking water, low- or even unchlorinated water should be tested for fungi described as mycotoxin producers, particularly when drawn from lakes, rivers and wells, or from karst systems.

Conclusions

Due to the currently unresolved issues, such as lack of a uniform approach for fungal count and correct identification of isolates, future inclusion of fungi in states' or national legislations for drinking water quality remain unclear, but nevertheless necessary. Fungal presence in water should be carefully considered in construction of water networks, and in health-care institutions, particularly hospitals and intensive care units, where water-transmitted fungi can pose a serious health risk. European countries should be aware of the most common and frequently isolated opportunistic fungi. In cases where surface water is used as the main water source for the production of drinking water these are the genera *Penicillium*, *Aspergillus*, *Botrytis*, *Geotrichum*, *Mucor*, *Rhodotorula*, *Scopulariopsis* and *Trichoderma*. Groundwater derived tap water can be the source of fungi of the genera *Alternaria*, *Aspergillus*, *Phialophora*, *Cyphellophora*, *Exophiala* and *Paecilomyces*. The most commonly detected fungi at consumers' endpoints, unregarding

the raw water source are *Rhodotorula*, *Alternaria*, *Mucor*, *Paecilomyces*, *Phoma*, *Aureobasidium*, *Trichoderma*, *Fusarium*, *Acremonium*, *Aspergillus*, *Penicillium*, and *Cladosporium*. These genera represent the core fungal biota of European tap waters. They can have a significant effect on mixed biofilm formations, material degradation and consumers' health. However, any other fungal genera observed in excess numbers in a particular geographic area should be taken into consideration for quality assessment of drinking water. The following points are recommendations to lower fungal contaminants in distribution networks and downstream at the end-user's access points.

Lowering the Effect of Water-Borne Fungi on Construction of Water Networks

Although the 4MS initiative (4MS, 2011) is not a requirement, future materials should be tested for microbial colonization (including fungi) before being integrated in water transport networks. Materials showing high affinity for fungal colonization and degradation could be replaced with more stable ones. This would contribute to prolonged stability of residual chlorination effect, lower biofilm formation and slowing of material degradation. Summing up, such preventive measurements could lower the economic costs due to later construction repairs.

Lowering Effect of Water-Borne Fungi on Human Health

Fungal implications for health could be lowered with the use of end-point filtration systems in order to minimize aerosolisation of fungal particles in drinking water. Such systems are particularly highly recommended for hospitals and healthcare facilities where people with impaired immune systems stay for prolonged times. Concentrations of mycotoxins in drinking water are presumably low, but should be monitored in cases of natural emergencies, such as prolonged floods or droughts that can promote fungal growth in water systems. Additional chlorination, in particular of surface water used as raw water source may nullify the toxic effect of certain mycotoxins and is thus recommended in cases of natural disasters, but also for small water treatment plants operating with surface water or water of mixed origin.

Biodeterioration, Fungi and Cultural Heritage

Several definitions have been suggested for biodeterioration, generally considered as “any undesirable change in a material brought about by the vital activities of organisms” (Sterflinger and Piñar, 2013). This can translate into physical and/or chemical damage and, as the title of this article states, the affected materials or objects may be deemed with historic, artistic and economic relevance and classify as Cultural Heritage (Griffin *et al.*, 1991). Fungi (as bacteria, archaea and lichens) assume an important role here and are virtually everywhere and colonize virtually any material, be it ancient or modern, private or public, organic or not (Sterflinger and Piñar, 2013). Because they are ubiquitous, the study on the influence fungi have on works of art or cultural heritage involves analyzing the dynamics established between them and a vast set of artistic supports: e.g., canvas, paper, parchment, wood, textiles, murals, or stone. It would be impossible to address all of these in this chapter but several reviews can be consulted for further reading (Choi, 2007; Coutinho *et al.*, 2015; Gaylarde *et al.*, 2003; Gu, 2003; McNamara and Mitchell, 2005; Pinheiro, *et al.*, 2019; Sequeira *et al.*, 2019; Sterflinger and Piñar, 2013; Warscheid and Braams, 2000; Zyska, 1997). Instead, the next lines will be dedicated to explaining the relationship between fungi and examples of organic and inorganic cultural heritage supports. After these examples, the issues of treatment and prevention are also addressed.

Fungal Biodeterioration Mechanisms and Impact on Cultural Heritage

Organic Supports: Paper Based Objects

Great part of the History of mankind is registered in the form of documents or works of art on paper support. Due to its hygroscopicity and organic content (mainly cellulose), paper is particularly susceptible to mycological deterioration. The source of raw material, additives and manufacture processes have greatly changed throughout papermaking history and these additions have also influenced its bioreceptivity, i.e., the proneness to colonization by living organisms (Guillitte, 1995). For instance, in order to reduce ink spreading and increase the bonding between fibers, paper was usually sized with polysaccharides, proteins or resins, like starch flour, gelatin or rosin, and ultimately alkaline synthetic compounds (Barrett, 1989; Hubbe and Bowden, 2009). Fillers, like clay or chalk were also added to the paper pulp to increase paper opacity (Cappitelli and Sorlini, 2005). These elements may constitute an additional and easier to absorb food source for fungi, and therefore strongly influence the intensity and results of fungal action on paper (Pinzari *et al.*, 2006).

Filamentous microfungi are considered the most important biodeteriogens of paper based collections due to their capacity to grow at average relative humidity (RH) levels (above 65%), to produce an array of deteriorating enzymes and metabolites (Sterflinger and Pinzari, 2012), and also due to the fact that fungal contamination is very easy to occur. Bacteria can also deteriorate paper materials, but since fungi require less moisture to develop, the environmental conditions normally found in libraries, archives or museums are more prone to the growth of fungi than that of bacteria.

When paper is colonized by fungi, besides the hyphae penetrating in the paper matrix causing physical alterations, several excreted metabolic products also accumulate in the material. Fig. 1 shows the cycle of fungal development and how it affects paper based cultural heritage assets but the same scheme can be applied to other substrates.

The decomposition of cellulose by cellulolytic fungi is mainly due to the production and secretion of a complex array of extracellular cellulases, which hydrolyze the cellulose macromolecule into small water soluble sugars that can then be processed by the fungi (Bergadi *et al.*, 2014). Other enzymes, like amylases or proteases decompose paper additives, causing loss of mechanical resistance. Non-enzymatic metabolites, like acids or metal ions also cause accelerated depolymerization of cellulose (Hastrup *et al.*, 2011). Furthermore, the biogenic formation of calcium oxalate crystals promoted by fungi can change the calcium carbonate alkaline reserve in paper and be a source of chemical and mechanical damage (Pinzari *et al.*, 2010).

The deterioration caused by all these fungal compounds will cause a gradual loss of mechanical strength in paper (Sequeira *et al.*, 2017). On an advanced stage of deterioration by fungi, paper acquires a felted consistency, with little or no mechanical resistance and its manipulation may result in losses of material and information (Fig. 2).

Besides chemical and physical damage, fungi often cause aesthetic alterations on paper through the production of colored pigments (Melo *et al.*, 2019), which interfere with the readability and aesthetic value of the object (Fig. 3).

The most commonly identified fungi from discolored paper/book materials (identified in more than five studies) are presented in Table 1.

Most species in Table 1 belong to the *Aspergillus* or *Penicillium* genus, both airborne conidia producers, with a high potential for dissemination and contamination. Almost all of these commonly identified fungi are great cellulase producers. It is also relevant to

Fig. 1 Life cycle of fungi and how they interact with paper-based substrates. The development of hyphae and formation of conidiophores/sporulation phases are visible to the naked eye and may affect readability and aesthetic value.

Fig. 2 Manuscript song book, 16th century, private collection. The felted consistency and colored fungal metabolites may be observed in greater detail in the right magnified rectangle.

highlight the presence in this table of important mycotoxin producers, such as *Stachybotrys chartarum* and *Chaetomium globosum*, which reinforces the importance of skin and respiratory tract protection gear when dealing with colonized paper collections.

Organic Supports: Photographic Collections

Photographic items are multi-layered materials composed of a wide assortment of constituents, generally having a common structure: a support layer (substrate) and a binder layer (emulsion) containing the microscopic image forming particles. Several photographic substrates have been used since the invention of photography in the early 19th century, such as metal plates, glass plates, cellulose nitrate, cellulose acetate, polyethylene terephthalate, or polyethylene naphthalene films, or paper (Roldão, 2018).

Fig. 3 Example of colored fungal stains on an etching (private collection).

The emulsion could be composed of albumen, collodion or gelatin (Pušková *et al.*, 2018). Silver, pigments or dyes were the most common picture forming particles used along history. Besides all these variations, photographic items can be delivered in several different formats, such as prints, negatives, slides, microfilm rolls or microfiches (Florian *et al.*, 1994). All these variables will contribute to the level of fungal bioreceptivity of photographic items, once favorable temperature and humidity growth conditions are met. Synthetic and semi-synthetic polymers, such as polyethylene and cellulose nitrate and acetate (substrates), respectively, are less biodegradable than natural polymers such as cellulose (paper substrate) or proteins (gelatin, albumin emulsion), and a closer similarity to natural polymers will result in a higher bioreceptivity for synthetic polymers (Gu, 2003). When comparing black and white (b&w) and color negatives and slides, a tendency for higher fungal susceptibility on color chromogenic materials was observed (Lourenço and Sampaio, 2009). Fungal growth was affected by the reduced silver particles in the b&w images, while the dyes in colored images had no significant impact on the fungi (Lourenço and Sampaio, 2009).

Fungi will degrade the photographic materials due to hyphae penetration in the photographic layers, by the excretion of specific enzymes and organic acids, decomposing the polymeric substrates and emulsions into smaller molecules, or by etching glass and metal plates supports to extract minerals or metallic ions. Fungi have also shown to alter the distribution of silver crystals in the gelatin-silver emulsions, reducing the silver ions and forming silver nanoparticles on the fungal cell wall (Sclocchi *et al.*, 2013).

Gelatin emulsions, for instance, are easily degraded by proteolytic fungi, leading to the solubilization and disintegration of the photographic image (Pušková *et al.*, 2018). As the emulsion or substrate are consumed by fungi, image material will be lost, causing significant disturbance or total loss of information in photographic objects. This is particularly relevant in objects that are meant for projection, like slides, in which a small fungal blemish will represent a large defacement on the image, when amplified and projected (Fig. 4).

In the last decades, a few studies have been published covering the fungal contamination of photographic collections, including gelatin-silver prints, albumen prints, film-based and glass-based negatives, slides, tintypes and ambrotypes (Table 2).

Most species belong to the common genera *Aspergillus*, *Cladosporium*, and *Penicillium* (Table 2). Only recently, culture independent fungal identification has been performed to identify the fungal species dwelling on photographic materials (Bucková *et al.*, 2014; Pušková *et al.*, 2016; Sclocchi *et al.*, 2017), bringing to light new fungal species, identified for the first time in these materials, such as species from the genera *Malassezia* or *Hyphodontia*. Nevertheless, mycological research on photographic collections is still scarce, and the biodeterioration mechanisms of such complex multi-layered materials are yet to be fully unveiled, along with proper conservation treatments to stabilize or reverse them.

Inorganic Supports: Stone Artefacts and Monuments

Deterioration of stone occurs through physical, chemical and biological processes, in isolation or in combination (Wakefield and Jones, 1998) and is intimately related to stone bioreceptivity and exposure to climatic conditions (Pinheiro *et al.*, 2018). So, against our primary impression that only organic based artefacts suffer from the action of microorganisms, stone, one of the materials used by mankind to express itself, is also susceptible to their action. In fact, microbial action can account for 20%–30% of stone deterioration (Wakefield and Jones, 1998).

Table 1 The most commonly identified fungal species in discolored paper/book materials – identification methods (CD – culture dependent; CI – culture independent; CDMB – culture dependent molecular biology), enzymes and color production

Fungal species	Identification methods			Colors	Enzymes
	CD	CI	CDMB		
<i>Aspergillus flavus</i> Link	(Nol <i>et al.</i> , 2001; Zotti <i>et al.</i> , 2008; Bankole, 2010; Borrego <i>et al.</i> , 2012; Castillo <i>et al.</i> , 2016)		(Oetari <i>et al.</i> , 2016; Okpalanozie <i>et al.</i> , 2018; Teixeira <i>et al.</i> , 2018)	yellow, green, orange	Cellulases (–/+++) Amylases (+/+++) Gelatinases (+) Proteases (+) (Das <i>et al.</i> , 1997; Gopinath <i>et al.</i> , 2005; Janda <i>et al.</i> , 2009; Pitt and Hocking, 2009; Samson, <i>et al.</i> , 2000; Saleem and Ebrahim, 2014; Anaya <i>et al.</i> , 2016; Oetari <i>et al.</i> , 2016; Okpalanozie <i>et al.</i> , 2018)
<i>Aspergillus fumigatus</i> Fresen.	(Das <i>et al.</i> , 1997; Nol <i>et al.</i> , 2001; Lourenço and Sampaio, 2005; Bankole, 2010)	(Di Bonaventura <i>et al.</i> , 2003; Krakova <i>et al.</i> , 2012)	(Mesquita <i>et al.</i> , 2009; Castillo <i>et al.</i> , 2016; Oetari <i>et al.</i> , 2016)	Turquoise-grey, dark green	Cellulases (+/+++) Amylases (+++) Gelatinases (+) Lipases (++) Proteases (Pasanen <i>et al.</i> , 1991; Das <i>et al.</i> , 1997; Tepsic <i>et al.</i> , 1997; Samson <i>et al.</i> , 2000; Chang <i>et al.</i> , 2004; Gopinath <i>et al.</i> , 2005; Janda <i>et al.</i> , 2009; Pitt and Hocking, 2009; Oyeleke <i>et al.</i> , 2010; Low <i>et al.</i> , 2011; Saleem and Ebrahim, 2014)
<i>Aspergillus niger</i> Tiegh	(Das <i>et al.</i> , 1997; Nol <i>et al.</i> , 2001; Lourenço and Sampaio, 2005; da Silva <i>et al.</i> , 2006; Michaelsen <i>et al.</i> , 2009; Bankole, 2010; Borrego <i>et al.</i> , 2012)		(Bergadi <i>et al.</i> , 2014; Oetari <i>et al.</i> , 2016; Pietrzak <i>et al.</i> , 2017; Coronado-Ruiz <i>et al.</i> , 2018; Krakova <i>et al.</i> , 2018; Okpalanozie <i>et al.</i> , 2018; Teixeira <i>et al.</i> , 2018)	Black/dark brown (melanin and hexahydroxyl pentacyclic quinoid colorants)	Cellulases (–/+++) Amylases (–/+++) Gelatinases (++) Proteases (+) (Fogarty and Kelly, 1979; Das <i>et al.</i> , 1997; Samson <i>et al.</i> , 2000; Parra and Magan, 2004; Gopinath <i>et al.</i> , 2005; Janda <i>et al.</i> , 2009; Jorgensen <i>et al.</i> , 2011; Borrego <i>et al.</i> , 2012; Bergadi <i>et al.</i> , 2014; Saleem and Ebrahim, 2014; Anaya <i>et al.</i> , 2016; Oetari <i>et al.</i> , 2016; Okpalanozie <i>et al.</i> , 2018)

Adapted from Pinheiro, A.C., Sequeira, S.O., Dinis, M.F.M., 2019. Fungi in archives, libraries and museums: A review on paper conservation and human health. Crit. Rev. Microbio. doi:10.1080/1040841X.2019.1690420.

Stone bioreceptivity is higher on stones with higher values of open porosity and water absorption by capillarity rise (Miller *et al.*, 2006, 2010). Adhesion and settlement of organisms are also crucial aspects and these translate into surface roughness (Miller *et al.*, 2012).

Among the most frequent agents of biodeterioration of stone are algae, cyanobacteria, bacteria, lichens and, of course, fungi. Each of these microorganisms displays biochemical features that allow them to damage stone substrate, something called biochemical deterioration (Griffin *et al.*, 1991). And chemically, fungi produce a vast array of acids and these allow fungi to weaken and dissolve the stone matrix. This effect may, however, vary between fungal species and different mineral substrates (Cadd, 2007). Many of such acids, such as lactic, oxalic or gluconic can etch the stone and function as chelating agents, solubilizing and dragging cations out of the stone matrix in a process known as leaching (Griffin *et al.*, 1991). Oxalic acid, one of the most common organic acids excreted by fungi and calcium oxalate (as whewellite and weddellite, both responsible for the appearance of a yellow-brown film on stone), have been observed in close proximity to fungal hyphae in situ (Pinna, 1993; Wakefield and Jones, 1998). Being (mostly and in normal conditions) aerobic organisms, fungi also produce carbon dioxide which becomes carbonic acid when in contact with water or moisture and this contributes to dissolution of the stone and soluble salt formation (Griffin *et al.*, 1991).

Fungi can also act mechanically upon stone. Their hyphae can infiltrate more or less deeply into the stone substrate (Griffin *et al.*, 1991) and cycles of swelling and shrinkage ease water seepage which increases the inflicted damage when it freezes and thaws inside the stone (McNamara and Mitchell, 2005). Hyphae also make way for the transportation of organic compounds and nutrients making it an enticing environment for bacteria to thrive (McNamara and Mitchell, 2005). The forces exerted by hyphal progression can lead to substantial disruption of the stone matrix, lifting and flaking stone surface applications such as paint, pigment and consolidants (Wakefield and Jones, 1998).

Several reviews have been elaborated on the relationship between microorganisms and stone monuments (Gaylarde *et al.*, 2003; Griffin *et al.*, 1991; McNamara and Mitchell, 2005; Warscheid and Braams, 2000). Many studies separate the members of stone microbial communities since each displays specific traits, but studying them as community is also insightful since synergies appear to take place early on in order to assure the communities survival in the sometimes harsh stone environment (Wakefield and Jones, 1998).

The microbiological communities that normally act on stone develop in a succession. Fungi are heterotrophic and require the presence of organic material prior to their development (Griffin *et al.*, 1991). So, the microbial colonization of stones commonly starts with phototrophic organisms (such as algae, cyanobacteria, mosses and higher plants) which build up a visible protective biomass film enriched with carbohydrates, growth factors and antibiotics on an otherwise almost nutrient-depleted stone surface (Warscheid and Braams, 2000).

The chemolithoautotrophic (bacteria) and chemoorganotrophic (bacteria and fungi) microorganisms follow these first colonizers. While the first group is especially relevant for the transformation of inorganic compounds into acids (such as nitric, sulfuric and nitrous, which they later release into the stone) the chemoorganotrophic group uses organic substrates as energy source and release their also very corrosive organic acids (Warscheid and Braams, 2000). In general, fungi use a slightly narrower range of carbon-based substrates than bacteria and present a larger cell mass which enables them to accommodate considerable enzymatic machinery and produce a wide variety of potential stone deteriotogens (Wakefield and Jones, 1998). These chemoorganotrophic fungi are able to penetrate into the rock material by hyphal growth and are usually found in stone crusts. They exert their biochemical activity due to the excretion of organic acids or by oxidation of mineral-forming cations, preferably iron and manganese (Burford *et al.*, 2003).

The type of fungus present in stone is related to the surrounding climate. The common airborne fungi – *Alternaria*, *Aspergillus*, *Cladosporium*, *Epicoccum*, *Aureobasidium*, *Phoma* and *Ulocladium* – are usually present in humid and moderate climates (Pinheiro *et al.*, 2018). *Exophiala*, a black yeast, has also been identified in stone (Warscheid and Braams, 2000) and when water and nutrient availability is reduced, lichens, black yeasts and microcolonial fungi – such as *Capnobotryella* – start to appear (Scheerer, 2008; Sterflinger and Piñar, 2013). Dematiaceous fungi (black fungi) are frequent in many stone types where they resemble carbonaceous deposits, which hampers their correct identification. By excreting melanins, they are responsible for the discoloration of stone surfaces and darkening of gypsum crusts (Wakefield and Jones, 1998; Warscheid and Braams, 2000). These melanins are persistent and function as a protection against UV radiation, predation, desiccation and increase cell resistance to pressure (Wakefield and Jones, 1998).

The aesthetic impact alone of the variations in color and texture of stone colonizers is an impetus for stone treatments such as cleaning or biocide application (Wakefield and Jones, 1998). At this point it is relevant to point out the ability exhibited by fungi to attack polymeric substances, including the ones conservators use for protective reasons: by-products of natural or synthetic substances applied during restoration treatments can act as a carbon source (Crispim and Gaylarde, 2005; Pinna, 1993; Scheerer *et al.*, 2009; Skipper and Skipper, 2014; Wakefield and Jones, 1998). This adds to the importance fungal contamination assessment has for stone cultural heritage (Warscheid and Braams, 2000) since the establishment of an heterotrophic community becomes possible even without the participation of phototrophs. After the community has been identified measures to reduce their impact and prevent further damage include reducing water exposure and nutrient obtainability. Biocides may be applied after compatibility tests are performed and care must be taken as artificial selection can clear the way for one species to take over (Warscheid and Braams, 2000) (see Section “Treatment and Preventive Measures for Fungal Contamination in Cultural Heritage” for more details).

Inorganic Supports: Ceramics and Glazed Tiles

Traditional ceramics are clay-based and, putting it in simple terms, are made of clay mixed with water and shaped during the forming process. After this is achieved the object is left to dry in order to become harder and submitted to fire for permanent

Fig. 4 Color slide colonized by filamentous fungi – left: full image; right: detail, where image loss is already observed. © Nederlands Fotomuseum/Ed van der Elsken, Photo credits: Katrin Pietsch.

hardening. Both type of raw materials and temperature used to harden the ceramic body are extremely relevant in the final composition, texture and porosity. Sometimes, the final product receives a finishing coating: engobe (colored coating of fine-grained clay that is applied over the ceramic body to reduce surface roughness) or glaze (vitreous coating used to enhance mechanical strength). Glaze finishes are more common on floor and wall tiles. One of the most beautiful elements used in built Cultural Heritage is the glazed wall tile which, by Near East influence, gained great importance in Portugal, Spain and later in Brazil (Coutinho *et al.*, 2015; Oliveira *et al.*, 2001; Pereira *et al.*, 2009).

Biological deterioration and its extent in glazed wall tiles is, as happens in stone, dependent on a series of preexisting conditions. Rainwater, sun heat, air currents and pollution affect outdoor glazed ceramics while inside microclimatic conditions such as liquid water and vapor ascending through the porous system of the ceramic body may also give rise to pathologies. A network of fissures is formed, soluble salts may arise on the surface and the glaze fracture is followed by subsequent detachment (Silva *et al.*, 2013a,b). Characteristics of the substrate are also worth mentioning. As also happened with stone, porosity and surface roughness play key roles in determining primary bioreceptivity in glazed wall tiles but because these are coated with a crystalline phase embedded in a glassy matrix this impermeable coating is very smooth. Pristine glazed materials tend to display a higher resistance to microbial colonization (Coutinho *et al.*, 2015). Of course, this changes once the substrates show the effects of environmental conditions and they become liable to the development of microorganisms. The microorganisms encountered in architectural ceramics, glazed tiles included, are similar to the ones mentioned for stone. A dark tarnishing detected on 19th century outdoor polychrome tiles in Brazil was attributed to Cyanophyte and Bacillariophyte algae (Oliveira *et al.*, 2001; Silva *et al.*, 2013a,b), colored alterations noticed in 20th century polychrome tiles covering the facade of an “Art Nouveau” building in Italy were attributed to cryptoendolithic cyanobacteria (Silva *et al.*, 2013a) and algae/fungi may give rise to green stains, particularly in blue-and-white glazes from the 16th to the 18th century (Silva *et al.*, 2013b).

Unlike stone and other substrates and despite being described as a common malaise very few studies have sought to identify the colonizing microorganisms on outdoor ceramic materials along with their mechanisms and effects (Coutinho *et al.*, 2015; Sand, 1997) on outdoor ceramic materials. The less studied ceramics typology are the glazed wall tiles (13%) but because these are classified as cultural heritage the relevance of these studies gains importance and they are predicted to increase in future times. Also, being classified as cultural heritage means such assessments on glazed wall tiles can trace an eventual association between a given community and the tile’s composition, since this is known and crucial before any conservation intervention. Eight studies are presented in the review by Coutinho *et al.* (2015) and include bacteria, cyanobacteria, algae and fungi. Nonetheless, lichens and bryophytes can also be found. Regarding fungi, Table 3 presents the species or genera identified in glazed tiles, the method used to identify them and the reference study.

Most are Ascomycota (90%) and only a minor part is represented by Basidiomycota. The fungi *Alternaria*, *Aspergillus*, *Fusarium*, *Penicillium* and *Phoma* were also detected in bricks (not shown). Based on the fact they are widespread airborne fungi with a large capacity to survive in different environments, their presence in all substrates is not surprising. Fungi display the wider diversity when compared with other ceramic architectural feature, such as bricks and roofing tiles (Coutinho *et al.*, 2015).

Lichens are also worth mentioning when discussing glazed tiles (and stone, for that matter). They consist of algal and fungal cells in close association, forming a large thallus which is visually detected, hence its importance in cultural heritage. Lichens are associated with the formation of a calcium oxalate patina (McNamara and Mitchell, 2005; Sabbioni and Zappia, 1991) resulting from the reaction of oxalic acid with the matrix. Although the release of corrosive acids is seen as damage inducing in this case this patina can help prevent the colonization by black fungi (Ascaso *et al.*, 1998; Pinna, 2014) (Fig. 5).

As happens for other materials used to create Cultural Heritage and on which biodeterioration occurs, the use of classic culturing methods coupled with molecular methods delivers a more trustworthy scenario (Coutinho *et al.*, 2015, 2013;

McNamara and Mitchell, 2005; Sequeira *et al.*, 2019). Classic culturing methods give us insight on the viability of the fungal community as well as allowing the metabolic study of the identified species. However, because not all collected samples are composed of viable specimens and/or we may not be giving these specimens the right media to thrive, molecular biology protocols are programmed to, ideally, deliver us all the viable, unviable, dead and alive elements of the fungal population. Technique limitations such as DNA extraction, Polymerase chain reaction inhibition or preference for one species over the other or even overwhelming amount of data per sample (as is the case when using NGS to identify entire communities) are some of the reasons why a polyphasic approach, such as the one performed by Coutinho *et al.* (2013) and mentioned in Table 1, is preferable. SEM imaging is perfect to detect if a fungal element is present in a damaged or corroded area of the artefact but is very hard to achieve an identification by its sole use.

Treatment and Preventive Measures for Fungal Contamination in Cultural Heritage

It is now an accepted fact that fungi cause severe chemical and physical damage on virtually all supports used to create cultural heritage. Some of them were described above. The defacing and eventual loss of reading urges those responsible to prevent fungal contamination altogether, diminish its impact or recover the damaged artefacts.

The costs increase substantially once there are “infected” artefacts or spaces and there is a need to advance to treatment options (Sterflinger and Piñar, 2013). The chemical methods available to perform this are restricted by two rules: (1) they must be

compatible with historic materials and (2) they must comply with health and environment regulations. Few fall within this scope (Sequeira *et al.*, 2012). One of the most famous biocides used to treat fungi contaminated documents was ethylene oxide, very effective but also very damaging and toxic (Sequeira *et al.*, 2012). Its effects can still be noted today when fumigated books are opened for reading or conservation purposes.

A biocide treatment also brings an additional concern. Very often, as shown in Section “Fungal Biodeterioration Mechanisms and Impact on Cultural Heritage”, there is a mixed community of microorganisms and their susceptibility to the biocide applied varies. It is fairly easily to understand the selective pressure this puts on the microbial community, and the Lascaux Cave is a perfect example of the effects successive biocide treatments can have: the over development of white fungal stains by *Fusarium solani*, *Pseudomonas fluorescens* (a bacteria), and black fungal species such as *Ochroconis lascauxensis*, *O. anomala* and *Exophiala castellanii* (Sterflinger and Piñar, 2013).

As far as physical methods are concerned, gamma radiation is very effective against fungi and their spores (Silva *et al.*, 2013a). However, the necessary dose to achieve the desired results must be in excess of 10–20 kGy and so this method may also affect many historic materials. So, for the time being gamma radiation is restricted to specific cases and must be closely monitored not just for its safety but also to measure its effectiveness. And so is the case for anoxia and heat/cold or modification of light treatments (Sequeira *et al.*, 2012; Sterflinger and Piñar, 2013).

Prevention-wise, performing periodic biological contamination assessments and monitoring the cultural heritage assets is pivotal (de Carvalho *et al.*, 2018; Silva *et al.*, 2013a). To effectively prevent fungal damage it is also necessary to assure climate control and frequent cleaning (Sterflinger and Piñar, 2013). Measuring RH and temperature on the environment surrounding a material can provide a generic indication of the risk of microbial biodeterioration, but care must be taken since these measurements are usually performed in a determined area of collections repositories, not reflecting the conditions in every niche and corner. Local microclimates with very high water activity can be generated by ineffective ventilation and surface temperature inhomogeneity in a room with an otherwise low RH (Sterflinger and Pinzari, 2012). Also, in already colonized materials, the humidity preserving biofilm will help fungi survive in lower environmental HR (Camuffo, 1998). By keeping the water activity of cultural heritage materials under 0.60, and temperature less than 20°C, with a good air circulation, the development of fungi can be avoided (Allsopp *et al.*, 2004; Arai, 2000; Florian, 2002; Raschle, 2001; Valentin, 2010). Nevertheless, the technology and/or building characteristics needed for an efficient climate control are not available to all the heritage repository institutions in the world.

UNESCO (2007) considers climate change as one of the most serious threats impacting on the conservation of cultural heritage. With climate change, the intensity, frequency and seasonality of extreme events, such as intense rainfall or floods, are projected to increase, together with a rise in global mean temperatures. This will lead to an increased risk of biodeterioration, even in altitudes and latitudes that may not have been previously concerned by such threats (UNESCO, 2007). This increased risk intensifies the need for an urgent development of control and mitigation strategies to protect our cultural heritage from biodeterioration.

Introduction

Indoor air quality (IAQ) includes biological and non-biological components that can affect the health and wellbeing of humans (Awad *et al.*, 2018). The biological components of the air in a building (such as the mycobiota) can cause a number of health problems, including immunologic reactions, toxicity, infection, and irritation (Awad *et al.*, 2018; Seltzer and Fedoruk, 2007). As such, the air quality in indoor buildings is of the utmost importance (Aydogdu *et al.*, 2005).

The microorganisms in indoor air have different sources, mostly outdoor air or anthropogenic sources, but, and because fungi can use all organic materials, including building materials, they thrive in an indoor environment, especially in humid conditions (Salonen *et al.*, 2015; Awad *et al.*, 2018).

The IAQ becomes even more important when we focus on buildings like schools, due to the commonality of respiratory illnesses in children, especially asthma (Aydogdu *et al.*, 2005; Su *et al.*, 2001). Several factors can be connected with childhood asthma, including environmental factors; also, it has been shown that children who live in damp and moldy buildings have more respiratory symptoms than children who live in less damp places (Su *et al.*, 2001). Because children have been shown to spend about 85% of their time in either school or at home, it is very important to study the air quality in both these dwellings (Su *et al.*, 2001).

Additionally, the association between moisture damage in school buildings, microbial presence due to excess moisture and the adverse health effects has been described previously (Aydogdu *et al.*, 2005; Hussin *et al.*, 2011; Meklin *et al.*, 2002). Still, there are no health-based guidelines for indoor dampness or microbial contamination (Karvala, 2012; WHO, 2009).

Because young children are more vulnerable to exposure to their environment than adults, and because fungal contamination can be used to assess the quality of indoor air, studying the fungal contamination in a building, in this case school buildings, is one way to assess the IAQ in schools (Cabral, 2010; Awad *et al.*, 2018).

This study aims to perform a scope review regarding the fungal contamination assessments performed on school's indoor environment and to determine a protocol for fungal contamination assessment to be used by the competent authorities and researchers.

Materials and Methods

This study reported the search of available data published between January 1st, 2000 and December 31st, 2018. The initial search terms were developed to identify research in the IAQ assessment in scholastic environments, focusing on the fungi contamination assessment. The databases chosen were PubMed, Scopus and Web of Science (WoS). Searches were carried out in English. The search terms via PubMed were "fungal contamination in school environments". This search strategy led to 3573 papers in all databases. Articles that did not meet the inclusion criteria and duplicates were excluded from further analysis (Table 1).

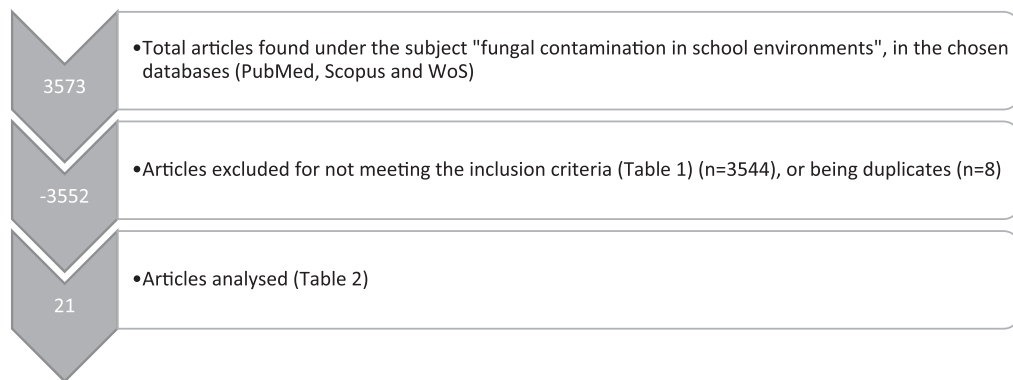

The diagram describes the different phases of the selection of papers (Fig. 1).

Results

A total of 21 articles were analyzed. Air sampling was performed with different techniques in the different studies, most commonly by active air sampling through impaction method (9 out of 21 studies) (Dacarro *et al.*, 2003; Viegas *et al.*, 2010; Hussin *et al.*, 2011; Roda *et al.*, 2011; Chen *et al.*, 2012; Rojas and Aira, 2012; Madureira *et al.*, 2015; Salonen *et al.*, 2015; Hoseinzadeh *et al.*, 2017), or two or more complementing techniques (in 6 out of the 21 studies) (Santilli and Rockwell, 2003; Wilson *et al.*, 2004; Godwin and Batterman, 2007; Cai *et al.*, 2009; Norbäck *et al.*, 2016; Awad *et al.*, 2018). Other techniques used for air fungal contamination assessment included air filtration (Santilli and Rockwell, 2003; Godwin and Batterman, 2007), settled dust (Santilli and Rockwell, 2003; Cai *et al.*, 2009; Norbäck *et al.*, 2014, 2017; Awad *et al.*, 2018), electrostatic dust collector (Vesper *et al.*, 2015), spore traps (Wilson *et al.*, 2004), surface swabs (Wilson *et al.*, 2004; Cai *et al.*, 2009; Norbäck *et al.*, 2016), tape lift method (Wilson *et al.*, 2004), and open plate method (Aydogdu *et al.*, 2005; Aydogdu and Asan, 2008; Norbäck *et al.*, 2016; Reddy and Srinivas, 2017).

Table 1 Inclusion and exclusion criteria in the articles selected

Inclusion criteria	Exclusion Criteria
Articles in English language	Articles in other languages (for articles)
Articles published from January 1st, 2000 to December 31st, 2018	Articles published prior to 2000
Articles published anywhere	
Articles related to fungi assessment in school environments	Articles related to biologic samples from students (exclusive)
Articles related to school environments up to high school (including kindergarten)	Articles containing information from university environments
Scientific original articles on the topic	Abstract of congress, Reviews/State of the art, reports: used for discussion
Identification of fungi to the genera level (at least).	

**Fig. 1** Phases of the selection of articles.

Fungal identification was performed by either morphological identification (in 14 out of the 21 studies) (Dacarro *et al.*, 2003; Wilson *et al.*, 2004; Aydogdu *et al.*, 2005; Aydogdu and Asan, 2008; Viegas *et al.*, 2010; Hussin *et al.*, 2011; Roda *et al.*, 2011; Chen *et al.*, 2012; Rojas and Aira, 2012; Salonen *et al.*, 2015; Hoseinzadeh *et al.*, 2017; Reddy and Srinivas, 2017; Awad *et al.*, 2018) or by fungal DNA detection (in 5 out of the 21 studies) (Cai *et al.*, 2009; Norbäck *et al.*, 2014, 2016, 2017; Vesper *et al.*, 2015), but never with both techniques. Also, in 2 of the studies, the fungal identification techniques were not sufficiently described (Santilli and Rockwell, 2003; Godwin and Batterman, 2007).

For all studies the most common fungal genera found were described, but some studies complemented this information with seasonal variations (4 out of 21 articles) (Aydogdu and Asan, 2008; Roda *et al.*, 2011; Reddy and Srinivas, 2017; Awad *et al.*, 2018), sampling site variations (2 out of 21 articles) (Godwin and Batterman, 2007; Roda *et al.*, 2011), and indoor/outdoor air contamination comparisons (10 out of 21 articles) (Dacarro *et al.*, 2003; Santilli and Rockwell, 2003; Wilson *et al.*, 2004; Godwin and Batterman, 2007; Aydogdu and Asan, 2008; Viegas *et al.*, 2010; Hussin *et al.*, 2011; Roda *et al.*, 2011; Salonen *et al.*, 2015; Awad *et al.*, 2018).

The most commonly found fungi genera were either *Aspergillus*/*Penicillium* (in 5 out of the 21 articles) (Godwin and Batterman, 2007; Cai *et al.*, 2009; Norbäck *et al.*, 2014, 2016, 2017), *Cladosporium* (in 5 out of the 21 studies) (Wilson *et al.*, 2004; Aydogdu and Asan, 2008; Viegas *et al.*, 2010; Chen *et al.*, 2012; Madureira *et al.*, 2015), *Penicillium* (also in 5 studies) (Aydogdu *et al.*, 2005; Roda *et al.*, 2011; Rojas and Aira, 2012; Salonen *et al.*, 2015; Hoseinzadeh *et al.*, 2017), *Aspergillus* (in 4 studies) (Santilli and Rockwell, 2003; Hussin *et al.*, 2011; Reddy and Srinivas, 2017; Awad *et al.*, 2018), or *Alternaria* (in 1 study) (Dacarro *et al.*, 2003).

From the ten studies that highlight the indoor/outdoor air contamination differences, three articles study only fungal species differences (Aydogdu and Asan, 2008; Viegas *et al.*, 2010; Hussin *et al.*, 2011), while two of them show higher fungal contamination in indoor environments (Dacarro *et al.*, 2003; Santilli and Rockwell, 2003), and five higher fungal counts outdoors (Wilson *et al.*, 2004; Godwin and Batterman, 2007; Roda *et al.*, 2011; Salonen *et al.*, 2015; Awad *et al.*, 2018) (Table 2).

Discussion

The present study focuses on the fungal contamination assessments performed in school environments made in the past twenty years. *Aspergillus*, *Penicillium*, *Cladosporium*, and *Alternaria* were the fungal genera most often described as dominant in the indoor air from all the selected papers. *Aspergillus* spp. was the most often connected with respiratory infections, as well as Mucorales order (Chowdhary *et al.*, 2016). Among *Aspergillus* genera, one of the most relevant concerns is their toxigenic potential (Viegas *et al.*,

Table 2 Data obtained from the chosen articles

Database	Title	Country	Environment description	Sampling methods	Fungal identification	Conclusions	References
PubMed	"Determination of aerial microbiological contamination in scholastic sports environments"	Italy	11 high school and college gyms in the province of Pavia, Italy	Air impaction	Morphological identification	Most common fungi during heated periods: <i>Alternaria</i> , <i>Cladosporium</i> , and <i>Penicillium</i> . Most common fungi during non-heated periods: <i>Alternaria</i> , <i>Aspergillus</i> , <i>Cladosporium</i> , <i>Epicoccum nigrum</i> , <i>Fusarium</i> , <i>Penicillium</i> , and <i>Phoma</i> . <i>Aspergillus</i> and <i>Epicoccum nigrum</i> were always present. Indoor contamination was always superior to outdoor contamination.	Dacarro <i>et al.</i> (2003)
	Fungal contamination of elementary schools: a new environmental hazard	USA	Two public schools in southern Connecticut.	Air impaction, filter cassette air sampling and settled dust		For school 1: In 70% of the indoor samples the fungal counts exceeded the outdoor values; <i>Alternaria</i> , <i>Botrytis</i> , <i>Curvularia</i> , <i>Epicoccum</i> , and <i>Stachybotrys</i> were detected only in indoor samples. <i>Aspergillus</i> , <i>Cladosporium</i> , and <i>Penicillium</i> were found both indoors and outdoors, but the levels of <i>Aspergillus</i> and <i>Penicillium</i> were higher in some indoor sites. For school 2: total mold spore counts ranging from 2600 to 9000 spores. m ⁻³ . The most affected rooms were the Special Education room and gymnasium.	Santilli and Rockwell (2003)
	Indoor air quality in Michigan schools	USA	Four elementary schools and five middle schools in southeast Michigan. Within each school, at least one art room, one miscellaneous use room, two classrooms, two science rooms, and two offices were selected.	Filter cassette air sampling	Morphological identification	Five mold genera were detected, with <i>Aspergillus</i> / <i>Penicillium</i> as the most common, followed by <i>Cladosporium</i> . For most species and schools, outdoor levels exceeded indoor levels, except for <i>Aspergillus</i> / <i>Penicillium</i> . Portable classrooms had higher bioaerosol concentrations than conventional classrooms.	Godwin and Batterman (2007)
	"Airborne fungi and bacteria in child day care centers and the effectiveness of weak acid hypochlorous water on controlling microbes"	Taiwan	Child day care centers	Air impaction	Morphological identification	Most commonly found fungi: <i>Cladosporium</i> , Yeast, <i>Nonsporium</i> , and <i>Penicillium</i> . Toxigenic <i>Aspergillus versicolor</i> and <i>A. flavus</i> detected.	Chen <i>et al.</i> (2012)

	Endotoxin, Ergosterol, Fungal DNA and Allergens in Dust from Schools in Johor Bahru, Malaysia- Associations with Asthma and Respiratory Infections in Pupils	Malaysia	Eight junior high schools in Johor Bahru, Malaysia.	Settled dust	Fungal DNA detection	Total fungal DNA and Asp/Pen DNA were found in all dust samples. <i>A. versicolor</i> DNA, <i>S. chartarum</i> DNA, and <i>Streptomyces</i> DNA were detected in 87%, 31%, and 31% of the classrooms, respectively. <i>S. chartarum</i> DNA was common in low levels.	Norbäck <i>et al.</i> (2014)
	Mold contamination in schools with either high or low prevalence of asthma	USA	A water-damaged school and a comparison school.	EDC sampling	Fungal DNA detection	Ten Group 1 molds, including <i>Aspergillus ochraceus</i> and <i>A. unguis</i> , were found in greater concentrations in the water-damaged school samples. Two Group 2 molds, <i>Aspergillus ustus</i> and <i>Cladosporium cladosporioides</i> , were significantly more abundant in the water-damaged school, while <i>Cladosporium herbarum</i> was more abundant in the comparison school.	Vesper <i>et al.</i> (2015)
	Ocular symptoms and tear film break up time (BUT) among junior high school students in Penang, Malaysia – Associations with fungal DNA in school dust	Malaysia	Eight junior high schools in Penang, Malaysia.	Settled dust	Fungal DNA detection	Fungal DNA and Asp/Pen DNA were found in all vacuumed dust samples. <i>A. versicolor</i> DNA was detected in 67% of the classrooms and <i>Streptomyces</i> DNA in 94%. <i>S. chartarum</i> DNA was found in one classroom (low levels).	Norbäck <i>et al.</i> (2017)
Scopus	Identification, Remediation, and Monitoring Processes Used in a Mold-Contaminated High School	USA	3-year-old high school	Air impaction, spore traps, surface swabs and tape lift sampling	Morphological identification	Fungal concentrations inside were lower than outside. <i>Cladosporium</i> sp. was the dominant fungi in the outside air. Inside counts reflected the outside counts.	Wilson <i>et al.</i> (2004)
	Airborne culturable fungi in naturally ventilated primary school environments in a subtropical climate	Australia	25 randomly selected primary schools in the Brisbane Metropolitan Area, Australia.	Air impaction	Morphological identification	Indoor fungi concentrations were lower than the outdoor concentrations. <i>Penicillium</i> most common fungi indoor, followed by <i>Cladosporium</i> and <i>Aspergillus</i> .	Salonen <i>et al.</i> (2015)
	Mold Allergens in Indoor Play School Environment	USA	Two play schools.	Open Petri-plate method	Morphological identification	Most common fungi: <i>Aspergillus</i> , <i>Cladosporium</i> , <i>Penicillium</i> , <i>Alternaria</i> , <i>Fusarium</i> , and <i>Curvularia</i> . Monsoon season showed less concentration of mold spores compared to winter season.	Reddy and Srinivas (2017)
Web of Science	Monitoring of Fungi and Bacteria in the Indoor Air of Primary Schools in Edirne City, Turkey	Turkey	Classroom, corridor, and canteen of five primary schools	Petri Plate Gravitational Settling Method	Morphological identification	<i>Penicillium</i> , <i>Cladosporium</i> , and <i>Alternaria</i> were the most common fungi.	Aydogdu <i>et al.</i> (2005)

(Continued)

Table 2 Continued

Database	Title	Country	Environment description	Sampling methods	Fungal identification	Conclusions	References
Airborne fungi in child day care centers in Edirne City, Turkey	Turkey		Classroom, sleeping room, and eating room of four child day care centers (CDCC)	Petri Plate Gravitational Settling Method	Morphological identification	The highest fungal concentration was found in June, and the lowest in January and February. <i>Cladosporium</i> , <i>Penicillium</i> , <i>Alternaria</i> , <i>Aspergillus</i> , <i>Epicoccum</i> , and <i>Stemphylium</i> were the most common genera, both indoor and outdoor, with differences in sequence.	Aydogdu and Asan (2008)
Quantitative PCR analysis of fungal DNA in Swedish day care centers and comparison with building characteristics and allergen levels	Sweden	Eleven	allergen-avoidance day care centers (AADCs) and eleven ordinary day care centers (ODCs)	Surface swabs and settled dust	Fungal DNA detection	Total fungal DNA was detected in 91%, Asp/Pen DNA in 34% and <i>S. chartarum</i> DNA in 6% of all rooms.	Cai et al. (2009)
Air fungal contamination in two elementary schools in Lisbon, Portugal	Portugal	Canteen,	library, and classrooms of two elementary schools in Lisbon, Portugal	Air impaction	Morphological identification	The two most commonly isolated fungi were <i>Cladosporium</i> sp. and <i>Penicillium</i> sp. The youngest school presented 8 different genera and the oldest presented 11 different genera. All the indoor spaces from both schools presented fungal species different from outdoor ones.	Viegas et al. (2010)
Characterization of Bacteria and Fungi Bioaerosol in the Indoor Air of Selected Primary Schools in Malaysia	Malaysia	Five	primary schools in Hulu Langat, Malaysia	Air impaction	Morphological identification	The most common indoor airborne fungi were <i>Aspergillus</i> , <i>Penicillium</i> , <i>Fusarium</i> , <i>Rhizopus</i> , and <i>Zygomycetes</i> .	Hussin et al. (2011)
Assessment of indoor environment in Paris child day care centers	France		Playroom and bedrooms of 28 Parisian child day care centers.	Air impaction	Morphological identification	Most common fungi were <i>Penicillium</i> and <i>Cladosporium</i> , followed by <i>Aspergillus</i> . Whatever the season, indoor total airborne fungal levels were higher in playrooms than in bedrooms, and outdoor total fungi levels were significantly higher than indoor levels. Levels of predominant genera were higher in hot season.	Roda et al. (2011)

Fungal biodiversity in indoor environments in Havana, Cuba	Cuba	One school in	Havana, Cuba	Air impaction	Morphological identification	<i>Penicillium</i> sp. was the most common species, followed by <i>Chrysosporium</i> sp.	Rojas and Aira (2012)
Assessment and determinants of airborne bacterial and fungal concentrations in different indoor environments: Homes, child day care centers, primary schools and elderly care centers	Portugal	50	classrooms in 9 child day care centers; 73 classrooms in 20 primary schools	Air impaction	Morphological identification	Most common fungi in child day care centers: <i>Cladosporium</i> sp., <i>Penicillium</i> sp., <i>Rhodotorula</i> sp., and <i>Aspergillus</i> sp. Most common fungi in primary schools: <i>Cladosporium</i> sp., <i>Penicillium</i> sp., <i>Rhodotorula</i> sp., and <i>Alternaria</i> sp.	Madureira et al. (2015)
Rhinitis, Ocular, Throat and Dermal Symptoms, Headache and Tiredness among Students in Schools from Johor Bahru, Malaysia: Associations with Fungal DNA and Mycotoxins in Classroom Dust	Malaysia	Eight	secondary schools in Johor Bahru, Malaysia.	Surface swab and open Petri dish sampling	Fungal DNA identification	Total fungal DNA and Asp/Pen DNA detected in all classrooms in both sampling methods. <i>A. versicolor</i> DNA detected in 70% of the Petri dish samples, while <i>S. chartarum</i> was found in 13% and <i>Streptomyces</i> DNA in 87% of the samples. <i>A. versicolor</i> DNA was detected in 56% of the swab samples, while <i>S. chartarum</i> DNA was detected in 3% and <i>Streptomyces</i> DNA in 28% of the samples.	Norbäck et al. (2016)
Indoor air fungus bioaerosols and comfort index in day care child centers	Iran	Four	different day care centers (DCC) all located at urban sites.	Air impaction	Morphological identification	The most common fungi were <i>Penicillium</i> spp. and <i>Cladosporium</i> spp.	Hoseinzadeh et al. (2017)
Air microbial quality in certain public buildings, Egypt: A comparative study	Egypt	Two	schools and two child day care centers.	Air impaction and settled dust	Morphological identification	Higher fungal concentrations were found in the winter indoors. <i>Aspergillus</i> , <i>Penicillium</i> , <i>Cladosporium</i> and <i>Alternaria</i> were the dominant fungi. Fungal concentrations were always higher in the outdoor environment, except in one of the primary schools.	Awad et al. (2018)

2019a). *Aspergillus flavus* is the main producer of the carcinogenic aflatoxin B1, and the cause for the most aflatoxin contaminations in food and feed; ochratoxin A, another mycotoxin with carcinogenic and neurotoxic potential, is also produced by several *Aspergillus* strains (Noonim *et al.*, 2008; Okoth *et al.*, 2018). Therefore, besides their infectious potential, *Aspergillus* species are also dangerous because of their toxigenic potential, hence the danger of their presence in school environments (Viegas *et al.*, 2019a).

Additionally, in the last couple of years, due to the improved knowledge on mycological infections, the number of species associated with health conditions has increased, including now *Fusarium*, *Penicillium*, and others; even though *Aspergillus* spp. are still considered to be the major cause of asthma with fungal sensitization, other fungi, such as *Alternaria* and *Cladosporium* spp., have been discovered to also be involved (Chowdhary *et al.*, 2016; Baxi *et al.*, 2016). Considering that these fungi were the most common found in schools, scholastic environments should be considered as areas with high risk of exposure to allergens and harmful fungal species.

Microbial air sampling falls under two categories: active air sampling (impaction, impinger or filtration) and passive air sampling (including surface sampling, dust analysis by settled dust collection (Santilli and Rockwell, 2003; Cai *et al.*, 2009; Norbäck *et al.*, 2014, 2016, 2017; Awad *et al.*, 2018) by EDC sampling (Vesper *et al.*, 2015), by open dish plate method (Aydogdu *et al.*, 2005; Aydogdu and Asan, 2008; Reddy and Srinivas, 2017; Norbäck *et al.*, 2016), by surface swabs (Wilson *et al.*, 2004; Cai *et al.*, 2009; Norbäck *et al.*, 2016), and other methods) (Haig *et al.*, 2016). Both categories have their advantages and disadvantages. Passive air sampling is usually more easily available, relinquishing in most cases the need for specific equipment, usually more economic and less obtrusive (Haig *et al.*, 2016). But these methods are not easily standardized, leading to difficulties when trying to compare the results obtained (Haig *et al.*, 2016). Active air sampling on the other hand is very easily standardized, because the equipment used can be programmed to draw a specific amount of air, leading to an easy report of the results (Méheust *et al.*, 2014). However, active air sampling is usually more expensive, since it requires specific equipment, and it can't describe the fungal contamination in an indoor environment for a long period of time, giving only an idea of the load in a specific moment (Viegas *et al.*, 2019b). Several different active and passive air sampling methods were applied in the different studies, but they were only applied jointly in some cases (Santilli and Rockwell, 2003; Wilson *et al.*, 2004; Godwin and Batterman, 2007; Cai *et al.*, 2009; Norbäck *et al.*, 2016; Awad *et al.*, 2018). A recent study in healthcare facilities in Portugal highlighted the need for the use of both sampling methods, because some toxigenic fungal species were identified only in specific sampling methods (Viegas *et al.*, 2019b). Therefore, when selecting a sampling strategy for schools environments, more than one sampling method should be applied to obtain a more accurate risk characterization (Viegas *et al.*, 2019a,b,c). Active sampling must be used in concurrence with the passive methods, with surface sampling to identify moldy spots on the walls and to assess the effectiveness of the cleaning, dust analysis (by either settle plate, EDC or settled dust vacuuming) to evaluate the fungal contamination/accumulation over time, and even the sampling of the HVAC filters in buildings that use artificial ventilation, in order to study the impact of the ventilation in the building's users (Méheust *et al.*, 2014). Thus, the analysis of HVAC filters can provide an idea of the fungal contamination in the air of buildings that use mostly artificial ventilation (Viegas *et al.*, 2019a).

When analyzing the samples obtained from either active or passive sampling, we can obtain different information, such as the fungal contamination or the presence of specific fungal compounds, such as mycotoxins (Méheust *et al.*, 2014; Viegas *et al.*, 2019c). The choice of what to analyze depends on the goal of the research, but when describing the contamination in a specific building, and because the same sample can be used for different analysis, it is important to obtain the most complete picture as possible, with information on all possible sources of pathogenicity for the occupants (Méheust *et al.*, 2014). This includes the analysis of the fungal contamination and the presence of the metabolites. Fungal detection can be performed by a vast array of methods, including the culture-based methods and microscopical identification, molecular detection, and biochemical testing (Méheust *et al.*, 2014). Culture-based methods and microscopic identification has been the gold standard for years, and is highly studied and applied, in not only academia but also in medicine (Kozel and Wickes, 2014). This method is easily applied in a high variety of samples, can be used for susceptibility testing, and it is relatively cheap (Kozel and Wickes, 2014; Méheust *et al.*, 2014). However, the microscopic identification requires a very well-trained user, and this method cannot detect the non-viable fungal load in the air (Kozel and Wickes, 2014; Méheust *et al.*, 2014). Molecular detection by PCR is a fast method and allows the identification of both the viable and non-viable fungal load in samples (Méheust *et al.*, 2014). However, this method requires a previous DNA extraction of the sample, is prone to contamination during the process, and the detection in environmental samples can be difficult, due to the contamination of the sample (Méheust *et al.*, 2014; Viegas *et al.*, 2019a). In all 21 studies, only one identification method was used, either morphological identification or molecular detection. Therefore, different analysis methods should be used when studying the indoor fungal contamination; indeed, the detection of specific fungal components, such as allergens or mycotoxins, is also important when describing the potential health effects on occupants (Viegas *et al.*, 2019b).

Out of the 21 studies, in only eight of them was the air sampling performed more than once (Awad *et al.*, 2018; Aydogdu *et al.*, 2005; Aydogdu and Asan, 2008; Chen *et al.*, 2012; Dacarro *et al.*, 2003; Hussin *et al.*, 2011; Reddy and Srinivas, 2017; Roda *et al.*, 2011). Several studies have shown that the fungal concentration in the indoor air of a building is influenced by meteorological factors (Reddy and Srinivas, 2017). Therefore, when establishing a protocol for fungal contamination assessment indoors (such as school environments), it is important to consider sampling in different months/seasons, depending on the climate of the region (Reddy and Srinivas, 2017).

Recently, a multi-approach sampling protocol using active and passive air sampling methods was applied in public health centers in Portugal (Lisbon) (Viegas *et al.*, 2019a,b). This study showed that, when using several passive air sampling techniques together, the qualitative assessment of the fungal contamination in the different centers was highly improved, with the identification of possibly pathogenic species in only one specific sampling method and in a specific media (Viegas *et al.*, 2019a,b). Considering that school

environments can be somewhat compared with health centers in the sense that they are highly frequented, and mostly by individuals with decreased immune systems (children in the case of schools, patients in the case of the healthcare centers), the use of different sampling techniques, different sampling media and even different fungal identification tools (culture-based and molecular) in concurrence is of the utmost importance when drawing a protocol for any public building.

The information drawn from the studies analyzed in this chapter, and others performed in different indoor environments (Viegas *et al.*, 2019a,b) allow the authors to suggest a protocol for sampling and analyses that should be considered when assessing the fungal contamination in a school environment:

- (1) Apply a checklist beforehand, taking note of the complaints of the users of the building relating to possible effects of fungal contamination (allergy/asthma symptoms, including coughing, wheezing, irritation in the eyes and nose area, etc.), the overall state of the building materials (cracks on the walls, visible signs of water damage, mold on the walls and ceiling, etc.), and the seasonal ventilation of the building (number of windows open, natural/ artificial ventilation, etc.) (Viegas *et al.*, 2019a).
- (2) Perform several sample collections throughout the year, considering the weather variations of the area. For example, consider hot and cold seasons, and even dry and wet seasons, to paint the most complex picture of the fungal environment of the building, and the weather-related variations of the contamination (Reddy and Srinivas, 2017).
- (3) Using a multi-approach sampling method that includes both active air sampling (impaction and impinger) and passive sampling, with surface sampling, settled dust, EDC, and even HVAC filters in buildings that use artificial ventilation (Viegas *et al.*, 2019a).
- (4) Analyze the samples by more than one method, to provide a more accurate characterization of the contamination, and to obtain information that goes beyond the fungal contamination, including information on the presence of allergens (very important in school environments), mycotoxins, and others.

In conclusion, the disparity between sampling and analysis methods between the studies of fungal contamination in school environments found highlights the need for a more comprehensive protocol when assessing fungal contamination in susceptible environments such as this one. The authors propose a multi-approach method that can yield the most thorough results out of the sampling in school environments, and that can be applied in other types of buildings.

Introduction

The fungi are ubiquitous and are found in many different environments including workplaces where they can be used deliberately (e.g., food industry) or not. Occupational fungal aerosols are associated with various immunoallergic or toxic respiratory disorders among workers (Eduard, 2009; Knutsen *et al.*, 2012) like asthma, rhinitis, hypersensitivity pneumonitis, organic dust toxic syndrome, and chronic bronchitis. A fungal aerosol is a complex matrix that depends on the investigated environments and that often presents a huge variety in particles sizes, in composition and in concentration. It may include different types of fungal particles such as spores, strands or fragments of mycelium that can be isolated or agglomerated. Such aerosols may be composed of culturable, viable, dormant or dead fungal cells and associated microbial compounds or metabolites such as (1,3)- β -D-glucans, mycotoxins, and allergens that can all be causative agents of workers diseases. Occupational environments may present a wide fungal biodiversity, composed of many different species. Fungal aerosols found in workplace atmospheres are even more complex because fungi are often mixed with other contaminants such as bacteria, dust or gas for example. Like airborne chemical pollutants, fungal concentrations are known to be highly variable over time including for a single working day, and in space within a company or even in a workshop. Measurements of airborne fungal concentrations in workplace atmospheres contributes to estimate the risks associated with workers' exposures, helps to better understand the complexity of occupational bioaerosols or may be used to check the effectiveness of control and prevention measures.

Usually, measurement methods consist of two main stages. The sampling aims to separate the airborne fungal particles from the air stream and to collect the pollutants on or inside a medium. The analysis of the sample aims to determine the quantity and/or the composition of collected fungal particles and associated compounds.

A lot of technical and scientific information is already available. Previous published articles and reviews well described the principles and mechanisms of collection involved in devices used for bioaerosol sampling (Verreault *et al.*, 2008; Grinshpun, 2010; Reponen *et al.*, 2011; Ghosh *et al.*, 2015; Haig *et al.*, 2016; Lindsley *et al.*, 2017; Reponen, 2017; Amato *et al.*, 2018; Mainelis, 2020) or aimed at presenting available methods for quantification and characterization of bioaerosols (Grinshpun, 2010; Ghosh *et al.*, 2015; Lindsley *et al.*, 2017; Mensah-Attipoe and Täubel, 2017; Duquenne, 2018; Fröhlich-Nowoisky *et al.*, 2018; King *et al.*, 2020).

The objective of this chapter is to provide an overview of the sampling and analysis methods actually used for measurement of fungi in workplace atmospheres. This inventory describes in a factual way the practices really implemented in more than 200 research works published between 2009 and 2019. This original and unusual approach aims to complement and to enrich the information already given in previous published reviews.

General Presentation of the Reviewed Articles

This work is not a systematic review but selected articles had to fulfill all of the following inclusion and exclusion criteria.

- The study was peer reviewed and published in English from 2009 to 2019.
- Measurements targeted, at least, one fungal aerosol parameter. Articles only focused on bacteria or viruses for example were not considered.
- Measurements were performed in, at least, one workplace atmosphere or occupational location. Thus, many environments were not considered, such as home, hotel, school, church, subway, railway station, neighborhood of an industrial site, outdoor urban or rural area (e.g., city, forest, garden, landscape), large-scale region (e.g., desert, Alaska, Antarctic, coastal area, troposphere, rain event), etc. Laboratory-based results (generation and characterization of experimental bioaerosols in a controlled chamber) were also excluded.
- Measurements of airborne fungi were performed using an active sampling device coupled with at least one offline method of quantification and characterization. Passive air sampling techniques (sedimentation settling plate, dust fall collector, passive electrostatic sampler, etc.) and surface sampling methods were not considered. Likewise, real-time detection techniques using biological particles fluorescence properties were also excluded.

The overview synthesizes data from 208 articles (the detailed list is available in online supplementary information SI). This corresponds to between 14 and 24 articles per year, coming from nearly 75 different peer-reviewed international journals.

Fig. 1 Number of articles vs. investigated occupational sector for the 2009–2019 selected articles (one study can provide either measurements of airborne fungal aerosols in only one workplace atmosphere, nor several).

Although not fully exhaustive, the reviewed articles represent however, a large part of the scientific published field studies on occupational fungal aerosols during the 2009–2019 decade.

These studies focused on numerous work environments grouped into 22 occupational sectors (**Fig. 1**). The most investigated types of workplaces belonged to the following main sectors: agriculture (poultry or swine facilities, horse stables, grain handling, greenhouses, slaughterhouses, dairy farms, etc.), composting (sewage sludge, green waste, food waste, etc.), solid waste treatment (waste collection, sorting facilities, municipal landfills, etc.), hospital and wastewater treatment. There is a strong inhomogeneity between those environments that led to several publications each year and other workplaces for which less than five articles were published in 10 years. If research studies and use of measurement methods improve knowledge about fungal aerosols and the resulting workers' exposures in some workplaces, **Fig. 1** also clearly shows that others occupational sectors were poorly documented during this decade. Otherwise, it can be noted that six of the nine most documented sectors (i.e., appearing in >10 articles) are considered in the scientific community as highly contaminated ([Eduard and Heederik, 1998](#); [Oppliger and Duquenne, 2016](#)) and show occupational situations with high exposures potential for workers: agriculture (animals and vegetables), composting, solid waste treatment, wood and food industry.

Overview of Active Samplers Used for Airborne Fungi Characterization in the Workplace Atmospheres

Through the 208 investigated articles, ~50 different bioaerosols samplers were used to perform airborne fungi field measurements. Over the 2009–2019 decade, we observed that little effort was made in scientific published works to standardize the usual practices of each team worldwide, making difficult the comparison of the results of different studies with each other. However, the complexity and variability of occupational fungal aerosols (particles sizes, composition, concentration, etc.) and the need to use suitable measurement strategies make it difficult to consider only one sampler as a reference method ([Mainelis, 2020](#)). If 72% of the articles used a single device to perform sampling of airborne fungi, 21% and 5% of them used two or three different samplers, respectively. Only three articles used four different fungal samplers in their sampling strategy.

These ~50 different samplers were classified into three large families (**Fig. 2**): the inertial impactors, which represent ~48% of the actually used sampling methods, the filtration samplers (~40%) and the liquid samplers/impingers (~12%). The principles and mechanisms of collection involved in these fungal samplers will not be described in detail as this information can be found elsewhere (some examples of published articles and reviews have been proposed in the introduction).

Fig. 2 Distribution of the ~50 different samplers used in the 2009–2019 investigated articles according to their principles of fungal particles selection/collection. The 18 cited samplers were used in ≥ 5 articles (e.g., GSP has been encountered in 18 different articles). The 35 others samplers that are not mentioned have each been used in only 1–4 articles throughout the 208 investigated published works.

Inertial Impactors

In impaction methods, fungal particles are separated from the air stream by their inertia: larger ones are collected on an impaction surface to be analyzed and smaller ones, that do not impact, follow the air stream towards the exit of the impactor or another downstream impaction stage.

~80 articles used 15 different models of single-stage culture-based impactors (the detailed list is available in Table S1 in SI). Many of them have been characterized for their physical collection and biological efficiencies or compared in term of performances. Such portable microbial samplers mainly differ in number, dimension or shape of inlet nozzles and jet-to-plate distance. The Reuter Centrifugal Sampler (RCS®) is specific because it is based on both centrifugal and inertial impaction forces for the biological collection on a manufacturer-supplied agar strip. The encountered air flowrates are also significantly different depending on the device: e.g., 10 L min^{-1} for the Burkard sampler for agar plates; 28.3 L min^{-1} for the 1-stage Andersen impactor/BioStage®; 100 L min^{-1} for the AirIdeal® 3PTM, MAS-100®, RCS®, Sampl'Air™ or SAS Super 100; up to 140 and 180 L min^{-1} for the M Air T® and SAS Super 180/Duo 360, respectively. Except for RCS, single-stage impactors are usually loaded with one standard 90-mm Petri dishes containing agar. Malt extract agar (MEA) and Sabouraud dextrose agar (SDA) were the collecting medium the most used in single-stage impactors. To a lesser extent, many different other types of agar were also used in a few articles: e.g., dichloran-glycerol agar (DG18), Rose Bengal agar (RBA), potato dextrose agar (PDA), Czapek-Dox agar, Wort agar, or Waskman agar. In ~50% of cases, the agar was supplemented with antibiotics such as chloramphenicol, streptomycin, penicillin and gentamicin as antibacterial agents to promote the growth of fungal species only. Agar's desiccation may be associated with single-stage impaction as moisture is removed by high air stream passing over the collecting medium plate. Consequently, the encountered sampling durations were most often ranged from 30 s to 3 min, and almost exclusively less than or equal to 10 min. Only five articles used durations greater than or equal to 15 min. However, the use of such short sampling periods remains of limited interest to extrapolate the average concentration levels over longer periods of several hours that could be more representative of full working time and thus of the real worker's exposure. Although the use of such single-stage impactors in highly contaminated sites can lead to overloaded culture plates and difficulties in enumeration due to overlap of colonies, we observed that they were used as much in non-industrial environments (hospital, office, laboratory, etc.) as in industrial sectors (composting, metalworking, animal farming, etc.).

A few articles used slit samplers (the shape of the impactor nozzle is rectangular) or spore traps (the detailed list is available in Table S2 in SI). Despite Hirst-type spore trap are mainly dedicated for collection of fungal spores and pollen grains, such impactors were not widely encountered in the investigated occupational field studies (Fig. 2). The air flowrates were between 5 and 15 L min^{-1} depending on the device. The impaction stage consisted of an adhesive tape or a coated microscope slide for direct microscopical investigations. Despite the Allergenco MK-III and the Burkard glass slide samplers were previously studied (Portnoy et al., 2000) and are frequently mentioned in bioaerosols reviews, these two inertial impactors have only been encountered once in the selected published articles for airborne fungi characterization in workplace atmospheres (see Table S2 in SI).

The 6-stage viable Andersen cascade impactor, one of the oldest bioaerosol samplers (Andersen, 1958), was also still the most used with 42 articles out of 208 (Fig. 2 and Table S3 in SI). Since a long time, this model of cascade impactor which has collecting stages with 50% cutoff diameter between $\sim 0.65 \mu\text{m}$ (lowest stage) and $\sim 7 \mu\text{m}$ (top stage) is widely used for determining the size distribution of

culturable microorganisms. Two other versions have been encountered in a few articles (see Table S3 in SI): a 2-stage and a 3-stage Andersen impactors. The expected air flow rate of Andersen cascade impactors (28.3 L min^{-1}) was correct in almost all the articles. Still to avoid drying of the agar or overloading of culture plates, the encountered sampling time was limited to 0.5–5 min for $\sim 80\%$ of the articles, while $\sim 20\%$ of them show sampling duration superior to 10 min. Highest sampling time of 30 min were only chosen in low concentration environments (office, laboratory and hospital). MEA was the collecting medium the most used in Andersen cascade impactors ($\sim 63\%$). Four other types of agar were also used in ~ 15 articles: RBA, SDA, PDA, and DG18. In a third of the works using the Andersen cascade impactor, the agar was supplemented with antibiotics to promote the growth of fungal species only. Only $\sim 60\%$ of the investigated articles clearly mention that they adjust the number of colonies counted on an agar plate using the positive-hole correction factor in order to take into account the fact that multiple fungi may deposit through an impactor hole (Macher, 1989). In the 208 investigated articles, only one work used another cascade impactor to measure the size distribution of fungal particles (Simon and Duquenne, 2014). It was a Marple that consists of eight impaction stages (34-mm Mylar® circular disks with six radial slots, 2 L min^{-1}) and presents cut-off aerodynamic particles diameters between 0.52 and $21.3 \mu\text{m}$, depending on the impaction stage.

Filtration Samplers

In filtration methods, fungal particles are collected by passing air stream through porous membrane filters, based on the five following mechanisms: inertial impaction, interception, gravitational settling, diffusion, and electrostatic attraction.

Because filtration may achieve high physical collection efficiency and remains an easy-to-use method to sample robust microorganisms such as fungi, the filter samplers are widely employed in the workplace atmospheres (Fig. 2). More than 15 different models were encountered in ~ 85 articles (the detailed list is available in Table S4 in SI). Some of them have long been known to industrial hygienists and are, despite some limitations (Görner *et al.*, 2010), representative of the inhalable fraction: GSP (3.5 L min^{-1}), Button (4 L min^{-1}), IOM (2 L min^{-1}), 25-mm or 37-mm closed-face cassette (2 L min^{-1}), PAS-6 (2 L min^{-1}) and 7-hole (2 L min^{-1}). Only one team, that considers that the thoracic fraction is the most suitable for describing the exposure of dairy farmers to organic dust, used thoracic filter samplers (see Table S4 in SI): CATHIA-T (7 L min^{-1}) and PPI-T (2 L min^{-1}). Only one work (Haatainen *et al.*, 2009) investigated the use of a size-selective polyurethane foam contained within a standard 2 L min^{-1} IOM to achieve the respirable fraction. Through the 208 selected articles, few of them sampled the fungal aerosols according to an environmental convention, using the following devices (Table S4 in SI): Personal Environmental Monitor (PM2.5 at 10 L min^{-1}) or PM10 static high-volume samplers ($500\text{--}3500 \text{ L min}^{-1}$).

In $\sim 20\%$ of the articles with filter samplers, it was not clearly specified which filter holder was used: e.g., “filtration system”, “filtration support”, “in-line filter holder”, “filter capsules” or sometimes just referred with the commercial name of the sampling pump or with a trade name for which no information seems available. We then created the following categories to list these unclear sampling methods (Fig. 2 and Table S4 in SI): 25-mm, 37-mm, or 47-mm filter support and just “filter support” when the filter diameter was not even specified. In such cases, the inlet or selection characteristics of fungal particles are unknown; no one can say if the measurement was done according to environmental conventions (PM10 or PM2.5), occupational conventions (inhalable, thoracic, respirable) or none.

Finally, the 2.5 kg portable AirPort MD8 sampler ($30\text{--}50 \text{ L min}^{-1}$) was used in a few articles (Table S4 in SI). The encountered sampling times were below ~ 30 min to try to avoid complete drying of the $3.0 \mu\text{m}$ pore size 80-mm gelatin membrane filter.

$\sim 5\%$ of the encountered sampling methods were cyclones (Fig. 2 and Table S5 in SI): e.g., GK 2.69 (1.6 L min^{-1}) for thoracic fraction, SCC1.062 Triplex (3.5 L min^{-1}) for PM1 fraction or different models of microcentrifuge-tube cyclones (1-stage BC112, 2-stage BC221, and BC251, between 2 and 4 L min^{-1}).

Filter samplers allow longer sampling times than agar plates’ impactors or liquid samplers, for example. For nearly 85% of the selected articles using a filtration method, the sampling time was between 15 min and 9 h; in $\sim 50\%$ of cases, the encountered sampling times were greater than 180 min. Such long period of sampling may lead to desiccation and loss of culturability of sensitive microorganisms (e.g., vegetative bacterial cells) but the biological efficiency is much better for resistant ones (e.g., fungi and others spore forming species). The sampling durations equal to or lower than 10 min were rare and exclusively associated with the use of a gelatin membranes. Only three studies use extremely long sampling times (> 20 h).

Polycarbonate was the collecting membrane the most used in filter samplers ($\sim 50\%$), followed by gelatin filters ($\sim 20\%$) and polytetrafluoroethylene (Teflon, PTFE – $\sim 12\%$). In $\sim 10\%$ of the articles which used filtration sampling, glass fiber filters were used, mostly to perform (1,3)- β -D-glucans analysis. Some other filter types were also used in a few articles: e.g., polyvinyl chloride (PVC), mixed cellulose ester, nitrocellulose and quartz microfiber.

Liquid Samplers/Impingers

Liquid samplers and impingers collect fungi directly into a liquid. Maybe due to several issues (liquid evaporation, possible need of periodic replenishments, re-aerosolization or internal losses of already collected material), liquid-based samplers were only used in $\sim 12\%$ of the investigated works to collect occupational fungal particles, known to be hydrophobic (Fig. 2).

~ 30 articles used 4 different liquid samplers (the detailed list is available in Table S6 in SI).

Coriolis family of samplers (mainly the Coriolis μ model) was used in 17 articles out of 208 (Fig. 2). Coriolis is a wetted-wall cyclone, which utilizes centrifugal impaction and swirling cyclonic mechanism to collect fungi into a liquid. In the investigated articles, it was frequently operated at flow rate of 300 L min^{-1} (200 L min^{-1} in only two works) and with 10 or 15 mL of collecting

liquid. Encountered in 8 articles, the BioSampler (12.5 L min^{-1}) is an all-glass swirling aerosol collector that utilizes centrifugal forces and tangential impingement into 20 mL liquid vessel as sampling principles (Willeke *et al.*, 1998). The All Glass Impinger (AGI-30, 12.5 L min^{-1} , 20 mL of liquid) (Han and Mainelis, 2012) and the CIP 10-M, that does not require an external pump for active sampling (10 L min^{-1} , 2 mL of liquid in a rotating cup) (Simon *et al.*, 2016), were found in ~ 5 articles each among the 208 selected articles.

About half of the encountered liquid-based samplers were filled with sterile distilled water and the other half with phosphate buffer saline (PBS) solution. In $\sim 50\%$ of these works, water and PBS were complemented with Tween-20 and Triton X-100, respectively. Other surfactant (Tween-80) and antifoaming agent were used in one and two articles, respectively. Despite viscous collection fluid could minimize evaporation and increase the sampling duration, only one investigated article used diluted mineral oil; this may be explained by the fact that the microorganism extraction is then often considered somewhat challenging.

For nearly 85% of the selected articles using a liquid-based collection, the sampling time was between 1 and 30 min; few others were included between 40 and 120 min. Such a majority of short sampling durations is mainly guided by the rapid evaporation of the water-based liquid rather than the objective of the study and the associated sampling strategy.

Static Versus Personal Sampling

Regarding the sampling strategies used in the 208 investigated articles or the large size of certain devices (e.g., single-stage or 6-stage Andersen impactors), static sampling ($> 80\%$) were more frequently encountered than personal sampling ($< 20\%$). For most static sampling points, samplers were positioned at around 1.5–1.7 m from the ground, the approximate height of the human respiratory tract. The personal samplers that were carried out in the workers' breathing zone (region within 30 cm of the worker's mouth and nose) were exclusively the following: Button, CFC, CIP 10-M, cyclones (Dorr-Oliver, GK 2.69, BC221, etc.), GSP, IOM, PAS-6, PPI-T. All these well-known aerosol samplers are not dedicated to fungi but are also commonly used for many years for sampling other particulate pollutants (wood dust, metals, dust not otherwise specified, etc.). Except for CIP 10-M which has a built-in pump and is used at 10 L min^{-1} , the others encountered personal samplers have air flowrates less than or equal to 4 L min^{-1} and need to be used with an additional personal sampling pump.

Overview of Downstream Analyses Used for Airborne Fungi Characterization in the Workplace Atmospheres

This bibliographic work provides a comprehensive view of the downstream analyses that are actually performed in scientific works to quantify/identify fungi and fungal components in the collected air samples from occupational atmospheres. The measurement principles of these analyses will not be described in detail as this information can be found elsewhere (some examples of published articles and reviews have been proposed in the introduction). ~ 20 different analysis methods were encountered and were classified into two large families (Fig. 3 and Tables S7 and S8 in SI): (1) culture-based methods comprising colonies' enumeration and identifications from culturable fungi and (2) culture-independent methods comprising microscopic analysis, qPCR and PCR, biodiversity and metabolites analyses. In the majority of the investigated articles ($\sim 52\%$), two different analyses methods were used. Then, 35% and 11% of the selected articles used one or three methods, respectively. Four different types of analysis methods used in the same work are few with only five articles concerned ($\sim 2\%$).

Fig. 3 Distribution of the ~ 20 different analyses used in the 2009–2019 investigated articles according to their principles of fungal particles detection. The 7 cited analyses were used in ≥ 5 articles (e.g., epifluorescence microscopy has been encountered in 19 different articles).

Fig. 4 Evolution of the proportion of the use of culture-based and culture-independent methods in the 208 selected articles during the 2009–2019 decade (one study can either provide measurements of airborne fungal aerosols using only one analysis, nor several).

Culture-Based Methods/Overview

In the 2009–2019 decade, culture was still the most used method to characterize fungi in workplaces (Figs. 3 and 4) and was used in ~80% of the 208 investigated articles. This analysis method enumerates the culturable fungi that are able to form colonies on agar medium in laboratory growth conditions (Mensah-Attipoe and Täubel, 2017). Fig. 4 seems to show a slowdown in the use of culture in recent years, with a decrease of ~30% between 2013 and 2019 throughout the considered articles.

Culture-Based Methods/Enumeration of Culturable Fungi

Analysis by culture is first associated with quantification of airborne fungal concentrations (expressed in number of colony forming units per cubic meter of sampled air, $\text{CFU} \cdot \text{m}^{-3}$). It can be done either directly by impaction on solid agar, the most used sampling method in combination with culture (68% of the articles in which culture is performed), nor indirectly using filtration or liquid samplers for which a volume of the eluate or the sampling liquid, or serial dilutions of it, is spread on the surface of agar medium. For a long time and despite known limits (Duquenne, 2018), such a quantification of the culturable fraction of the fungal community is considered as a first approach of the evaluation of the fungal contamination in the workplace atmospheres and/or of the workers' exposure.

For enumeration, different broad agar media, which support the growth of a wide number of fungi, were encountered. MEA was the most used with ~47% of the selected articles, followed by three other media observed in a similar proportion (~15%): RBA, SDA and DG18. To a lesser extent, some others media such as PDA or Blood agar were used in less than 10 articles. In ~40% of cases, these broad growth media were supplemented with at least one antibiotic, mainly chloramphenicol.

Culture-Based Methods/Identification of Culturable Fungi

In ~65% of the articles in which culture was done, a subsequent identification of the genera or species of the grown colonies was performed. Among the different methods that were used to identify culturable fungal isolates, description of macroscopic and microscopic phenotypes was the most frequently encountered (Fig. 5). Biomolecular, biochemical, and chemical identification methods were also used in ~30 articles. 34 articles used a combination of two or three of these different culture-based methods to perform the identification of fungi.

~53% of the identification methods performed were based on macroscopic and/or microscopic morphological criteria, most often after subculturing. Standard taxonomic keys, well described in previous reviews (Lindsley et al., 2017; Fröhlich-Nowoisky et al., 2018), were usually applied to perform the identification of culturable fungi: e.g., colonies morphology, ability to grow on selective media or specific temperatures to discriminate mesophilic and thermotolerant fungi. Microscopic observation also often helped to reveal which types of fungi are concerned. Stains (e.g., lactophenol cotton blue) were sometimes cited to examine fungal element and help to resolve these colony structures using microscopic-based approaches.

Identification of the cultivated fungi using their genetic material represented ~9% of the articles associated to culture (Fig. 5). Briefly, the principle of this technic is to extract DNA from pure cultures before amplifying the region of interest by polymerase chain reaction (PCR). The PCR products are then purified and sequenced. The sequence obtained are finally compared with existing sequences in databases using alignment software (Duquenne, 2018; Fröhlich-Nowoisky et al., 2018). Within these DNA-based methods, the

Fig. 5 Proportions of the different culture-based identification methods encountered in the investigated articles in which culturable fungi were measured (one study can either provide identification of culturable fungi using only one method, nor several).

nuclear ribosomal internal transcribed spacer (ITS) gene sequence of fungi was frequently used. The gene coding for β -tubulin to identify *Aspergillus* and/or *Penicillium* was found in a few articles (Roussel *et al.*, 2012; Plewa-Tutaj and Lonc, 2014). The D1–D2 region of 25S rRNA and the HKGF2 gene coding for β -tubulin gene was analyzed in only one article (Simon and Duquenne, 2014). Specific PCR followed by gel electrophoresis were done in two articles to identify species (Hansen *et al.*, 2010; Donát *et al.*, 2012).

Identification based on biochemical methods were almost exclusively performed with API™ miniature test. These tests are specifically used for yeast identifications (API 20C) and none are existing for filamentous molds. One article reported the use of Biolog™ with Microstation ID (Paba *et al.*, 2014). These miniatures systems consists of a wide range of phenotypic and metabolic tests to be performed providing metabolic profiles that are compared to a database containing profiles of known microbial isolates (Duquenne, 2018).

Identification based on chemical methods were used in only five of the investigated articles (~2.5%, Fig. 5 and Table S7 in SI). Four were using Maldi-TOF mass spectrometry method. The Maldi-TOF method compare the proteomic profiles obtain from pure culture to a database in order to identify the microorganism (Ghosh *et al.*, 2015; Duquenne, 2018). Gas chromatography method for studying fatty acid composition of the fungi was investigated in one article (Park *et al.*, 2011).

Culture-Independent Methods/Generality

Culture-based methods only target the fraction of airborne occupational fungi that remain culturable after sampling and laboratory analysis. Cultivation is known to dramatically underestimate the total population and the real diversity of environmental samples (Ghosh *et al.*, 2015). Therefore, a large part of the fungi as well as their components or metabolites cannot be detected or quantified with culture-based analyses. Not all the numerous different methods (e.g., microscopy, molecular techniques, flow cytometry, ATP assays, etc.) which are usually listed in classic reviews, were found in the present factual inventory work. ~100 of the 208 selected articles used one or several culture-independent analyses, alone or in addition to culture-based analyses.

Culture-Independent Methods/Microscopic Analysis

Various microscopic methods were used to perform enumeration of viable and non-viable fungi in occupational samples. Epifluorescence microscopy was the most used method (~56% of the articles using microscopy) and was often coupled with acridine orange for DNA staining. Other fluorochromes were used in a few articles: e.g., DAPI and Calcofluor-White. Widely used to count the total fungal spores expressed in spores · m⁻³, it was also sometimes associated to a total fungal count of both spores and hyphal fragments or a total airborne microorganisms count including bacteria and fungi.

Bright field microscopy was encountered in ~25% of the articles using microscopy and was often associated with spores traps/slit samplers (Hirst-type and Burkard glass slide sampler). Indeed, such samplers allows collecting fungal particles directly on a microscope slide to facilitate counting and observation. A further identification step was sometimes associated either with a germination step or by morphological criteria. In a few articles, eluate was spread directly on a slide, dried and stained using glycerin jelly to count fungal spores and identified them morphologically. In only one article (Cho *et al.*, 2011), the eluate was filtrated through a MCE filter that was placed on a glass slide, then made transparent and stained before counting.

Total fungal spores can also be count and characterize (e.g., size and morphology) using scanning electronic microscopy (see Table S8 in SI). More recently, fungal spores and/or submicronic and larger fungal fragments were observed and differentiated using field emission scanning electronic microscopy, with prior immunolabeling.

Culture-Independent Methods/Molecular Methods

The principle of these techniques are based on the extraction and purification of DNA from air sample without prior cultural step, and then on the amplification of the region of interest by PCR.

qPCR was used in 14 articles, mainly to quantify fungal aerosol from air sample. Specific qPCR for targeted species (as *A. fumigatus*) or genera (e.g., *Aspergillus*, *Penicillium* or *Alternaria*) were used in six articles (see Table S8 in SI). In three articles, quantification was performed without identification because using universal 18S rRNA or ITS primers for “total” fungi. In five other articles, qPCR was not performed to quantify but only to detect and identify some specific taxa (e.g., *A. flavus*, *A. fumigatus* and *A. ochraceus* in poultries). Specific PCR followed by gel electrophoresis was performed in one article to identify specific strain of *Trichoderma harzianum*. In many of the above-mentioned articles using qPCR and PCR, the sampling was performed using the Coriolis μ and its 300 L min⁻¹ flow rate.

DNA sequencing methods including Sanger, 454 pyrosequencing and Illumina sequencing platforms provided new insight into the characterization of fungal aerosol. In the 2009–2019 selected articles, such methods of biodiversity analysis allowed characterizing the fungal communities in various occupational sectors: e.g., composting, agriculture, coalmines, solid waste treatment, and hospital. Fig. 4 shows that, since 2014, the percentage of articles using these techniques is gradually increasing.

Pre-amplification PCR of the extracted and purified DNA contained in the air sample consists in the first step. Then, for diversity analysis, genes coding for ribosomal subunits 18S rRNA or ITS are often used as targets for PCR amplification. The fragments can be sequenced by classical techniques after PCR products being cloning or directly sequenced after TTGE or D-HPLC separation of PCR products (see Table S8 in SI). Since 2014, sequencing was mainly performed with high throughput sequencing (also called next generation sequencing) with 454 pyrosequencing or Illumina platforms (see Table S8 in SI). These methods permits in theory to detect all fungal taxa present in a sample independently of their culturability or viability. NGS results are then often presented as relative abundance of a given fungal taxon (Mensah-Attipoe and Täubel, 2017).

Based on sequencing with Illumina platforms, two articles used a metagenomics approach (whole genome sequencing) to study the total airborne microbial communities (see Table S8 in SI). It consists in the sequencing of all nucleic acid sequences of a complex sample by whole genome shotgun approach. Sequences are then reconstructed and identified by comparison with databases. One interesting work investigate the comparison of the diversity measured by ITS sequencing with Illumina with that obtained by a high number of fungal qPCR (Unterwurzacher et al., 2018).

Culture-Independent Methods/Metabolites Analysis

Fungal metabolites or other constituents are also frequently investigated because they can be measured as “molecular signatures” of the biological nature in the occupational atmosphere (Fröhlich-Nowoisky et al., 2018). 1,3- β -D-glucan, a polysaccharide found in the fungal cell wall under a triple helical structure and associated to potential health effects by inhalation (Grinshpun, 2010; Ghosh et al., 2015; Mensah-Attipoe and Täubel, 2017), was measured in 23 selected articles (see Table S8 in SI). Glucans were mainly quantified (~80%) by enzymatic assay with some commercial kits like GlucateLL or Fungitic g test, while a few studies used method based on immunoassay.

Ergosterol is the major sterol found in membrane of fungal spores and hyphae. As it is found almost exclusively in fungi, ergosterol is thus considered as a good indicator to evaluate total fungal biomass (Mensah-Attipoe and Täubel, 2017). This structural component was studied in three articles by gas chromatography to measure fungal contamination in occupational workplaces (see Table S8).

Mycotoxins, a secondary metabolite of fungi, is considered potentially harmful by inhalation. Moreover, identification of specific mycotoxins can help identify the presence of certain fungal species. In the selected articles, multi-mycotoxins (e.g., aflatoxin B1, ochratoxin A, deoxynivalenol, gliotoxin, zearalenone) were investigated by liquid chromatography to assess farmers (Lanier et al., 2010) and grain workers (Niculita-Hirzel et al., 2016) exposures.

ELISA method was used in one article (see Tables S8) to perform quantification of antigens from specific fungal species (*A. fumigatus*, *A. versicolor*, *P. chrysogenum*, *Cladosporium* spp.). Similarly, a new metaproteomic analysis of proteins present in bioaerosol from composting, wastewater treatment and agriculture (vegetables) environment was performed using nano-HPLC Tandem Mass Spectrometry in one article. It allowed the identification of proteins from different fungal species (e.g., *A. flavus*, *A. clavatus*, *C. albicans*).

Conclusion

Several previous published reviews aimed at exhaustively describing the existing measurement methods to characterize bioaerosols. Using an unusual approach that factually inventory the sampling and analysis methods actually used for measurement of fungi in workplace atmospheres, this work provides an overview of practices really implemented in numerous research articles published between 2009 and 2019.

The highlights of this complementary overview are:

- ~50 different active samplers and ~20 different offline analysis methods were encountered to measure fungal aerosols in work environments.

- The airflow rate for a given sampler, the collecting medium (filter, liquid, agar, etc.) and the sample preparation steps and analysis (agar, operating conditions, elution, reagent, processing time, etc.) can even be different from one study to another.
- Filter samplers (GSP, Button, IOM, closed-face cassette, etc.), single-stage impactors or 6-stage viable Andersen impactor were the most used sampling methods.
- Filter samplers were almost the only ones to be used in order to carry out workers' personal sampling and/or long-term sampling (> 180 min).
- A large number of selected articles did not clearly specify which fractions of the aerosol was targeted (inhalable, thoracic, respirable, PM₁₀, PM_{2.5}). Some articles also used imprecisely described sampler or unusual samplers' airflow rates leading to the sampling of an unknown fungal aerosol fraction.
- Despite known drawbacks, culture-based methods were still, by far, the most widely used analysis. Enumeration of fungal colonies was often associated with identification of species, most of the time using morphological criteria, leading to a first approach of the species present in workplace atmospheres.
- Characterization of fungal diversity, using NGS methods for example, was gradually increasing since 2014.

Therefore, as already stated by previous authors and due to diversity in the sampling and analysis procedures but also in the reporting protocols, the data comparison between published studies remains challenging and is sometimes impossible. Each single scientific article has its own sampling objectives and strategy; it can only provide incomplete results and a partial picture regarding presence, quantification, complexity and workers' health impact of occupational fungal aerosols. To date, it seems preferable to consider the contribution of several articles carried out in a given occupational sector as complementary without trying to compare them. It is of course desirable that, during the decade 2020–2030, the scientific community work together to develop better harmonized fungal aerosol measurement methods and reporting guidelines.

Fungal Contamination of Sawmills

Anne Straumfors and Anani Afanou, National Institute of Occupational Health, Oslo, Norway

© 2021 Elsevier Inc. All rights reserved.

Introduction

Fungi as Occupational Health Risks at Sawmills

Sawmills manufacturing sawn boards, timber frames, glulam, decking, flooring, joinery, fencing, and several other wood products exist across the world. Several thousand people are employed in the sawmill industry, including several European countries (Austria, Belgium, England, Scotland, Northern Ireland, Croatia, Denmark, Finland, France, Germany, Latvia, Norway, Romania, Sweden, Switzerland), Canada, USA, New Zealand, Australia, India, and several African countries ([Fig. 1](#), See “Relevant Websites section”). Only in the European Union, there are approximately 35,000 sawmills that employ about 250,000 people (See “Relevant Websites section”). Sawmill workers are exposed to wood dust and multiple wood-associated chemicals and microbiota, including fungi ([Straumfors et al., 2018](#); [Demers et al., 2000](#); [Douwes et al., 2000](#); [Duchaine et al., 2000a](#); [Eriksson et al., 1996](#); [Rosenberg et al., 2002](#)). Although several components in the sawmill aerosol can cause health effects, the exposure to fungal spores has been of particular interest, and is associated with respiratory symptoms and hypersensitivity pneumonitis (HP) among sawmill workers ([Wimander and Belin, 1980](#); [Eduard et al., 1992a, 1993](#); [Halpin et al., 1994b](#)). The severity of health effects resulting from fungal exposure and the number of workers this potentially includes, have received attention for decades and still rises concerns in the sawmill industry. Continuous exposure reduction and control will have great impact on both workers' health and the society's health economy.

The possible inhalable exposure to fungi along the process line of sawmills is dependent on the growth and occurrence of fungi, but also on the degree of fungal aerosolization, that is dependent on the work process, task, and technological installation. This review intends to discuss these factors and potential health outcomes linked to fungal exposure in sawmills.

Fungal Exposure in Sawmills

Many types of fungi accompany trees during natural life and decay, i.e., biotrophic, necrotrophic, saprophytic and endophytic fungi. Once the tree is cut, wood logs are stored in piles sorted by dimension on dedicated yards outdoors before debarking and cutting at the sawmills. During this time, the timber is kept humid so to stabilize the wood and prevent cracking. As a result, logs are often colonized by endogenous fungi, fungi from the local environment ([Dickinson and Levy, 1990](#); [Strong et al., 2005](#)) and bacteria ([Rossell et al., 1973](#)). A large part of the potential fungal contamination inside sawmills is avoided by debarking the logs before they enter the sawmill. Logs are cut into planks inside the saw department, and the green timber is sorted according to their dimension. After sawing, the green timber will be stored for a variable time length before it is further processed. In this period, fungi may continue to grow on the timber if the water content is high, as is often the case before kiln drying and during the first few hours in the drier. Dried timber with surface colonization is handled in the sorting of dry timber department, where the timber is sorted by quality and dimension. Although fungal particles, including spores and fragments, are released into the air and subsequently inhaled by workers at relatively high levels during handling of the timber at any stage in the sawmill process line, the transition between dryer and sorting of dry timber has been associated with the highest exposure. Dried and sorted timber are further processed at the planer department (see [Fig. 2](#) for an overview of the process line at sawmills). Maintenance and transport workers engaged in many stages of the process line.

A proper exposure assessment is necessary to evaluate health effects of work place exposure. Personal sampling is recommended for the quantitative determination of suspected agents. The methods for fungal aerosol sampling, detection, and quantification is decisive for the levels and details of reported fungal exposure in occupational settings. This will have impact on how we can evaluate health risk related to fungal exposure. In the following sections, the results of fungal exposure in sawmills is presented with some emphasis on the different methodology used in order to highlight this aspect.

Exposure Measurements and Identification by Cultivation of Aerosol Samples From Sawmills

A review of the literature shows that the average levels of fungal exposure in sawmills range between 0.8×10^3 and 50×10^3 CFU per m^3 when assessed by cultivation on artificial media followed by counting of colony forming units (cfu) ([Table 1](#)). Cultivation of fungal particles is the most common method for measuring fungal exposure in sawmills as this method is relatively cheap and enables both quantification (cfu counts) and taxonomical characterization based on of the macro morphological appearance of colonies, their characteristics in culture and light microscopic observation of the micromorphology ([Eduard and Heederik, 1998](#)). The cultivation of sawmill aerosols have shown that the composition of fungal species includes *Cladosporium* spp., *Alternaria* spp., *Aspergillus* spp., *Penicillium* spp., *Trichoderma* spp., *Paecilomyces* sp., *Rhizopus* spp. and *Mucor* spp. in sawmills in Canada ([Duchaine and Meriaux, 2000](#); [Cormier et al., 2000](#)), Croatia ([Klaric et al., 2012](#)), Poland ([Dutkiewicz et al., 2001a](#)), Italy ([Gioffre et al., 2012](#)), UK ([Halpin et al., 1994a](#)), and Norway ([Eduard et al., 1988](#)). The study from Croatia revealed the presence of *Chrysomya* *nitrophila*

Fig. 1 Sawnwood, coniferous production quantity by country. Average 2016–2018. (FAOSTAT 02.20).

in addition to *Penicillium* sp and *Paecilomyces* sp (Klaric *et al.*, 2012). Although cultivation is commonly used to assess fungal exposure, it is important to have in mind that results may be biased towards rapidly growing fungi that outcompete and inhibit slowly growing species (Wu *et al.*, 2000; Macneil *et al.*, 1995). Furthermore, since aggregates of many propagules will be counted as one colony and since many species are no longer cultivable after aerosolization, colony counting will underestimate the total number of fungal propagules in the air.

Exposure Assessment of Both Live and Dead Fungi by Microscopy

The use of fluorescence or scanning electron microscopy (SEM) to assess fungal exposure has the advantage of including non-viable and non-cultivable fungal particles. Fluorescence and confocal microscopy can be used for identification and quantification of fungal aerosols after staining with dyes (Green *et al.* 2005a,b) or fluorochromes (Palmgren *et al.*, 1986; Nayak *et al.*, 2011). To our knowledge, only Roponen *et al.* have used epifluorescence microscopy with the CAMNEA method to estimate fungal exposure in sawmills and reported personal exposure levels ranging between 2.15×10^5 and 14.6×10^5 spores per m^3 in a Finish sawmill (Roponen *et al.*, 2002; Table 1). The mayor limitation of this method is that the natural dense pigmentation of many spores may mask the fluorescence of the dyes employed from staining and lead to underestimations of the exposure (Burge, 1995).

The high resolution and field depth obtained by SEM enables the visualization of detailed characteristics of fungal particle surface morphology, shape and size. A rough estimation indicate that spore count with SEM gives averagely ten times higher counts as cfu counts (Eduard, 2009). Hence, quantitatively SEM may give more precise spore exposure estimates than cultivation. Since both viable/cultivable and non-viable/dead fungal particles have antigens, allergens, toxins and immune-modulating components such as β -1,3-glucans, SEM represents a generally broader health relevant estimate. SEM have been used to measure the exposure levels of fungal spore in several sawmill studies (Eduard *et al.*, 1993; Faerden *et al.*, 2014; Straumfors *et al.*, 2018; Dahlqvist and Ulfvarson, 1994). In a longitudinal study in the 1980s, Eduard *et al.* reported that wood trimmers were exposed to up to 10^7 spores/ m^3 , AM 4×10^6 spores/ m^3 (Eduard *et al.*, 1993; Table 1). Micro morphological recognition of spores from *Rhizopus microsporus* and *Paecilomyces variotii* in the samples were enabled by SEM comparison of spores from pure cultures. As such, wood trimmers' exposure was estimated to 1.3×10^4 *R.microsporus* spores/ m^3 and 130×10^3 *P.variotii* spores/ m^3 (Eduard *et al.*, 1993).

Over a period of nine years, Færden *et al.* observed a reduction in sawmill workers spore exposure, from AM 9.8×10^6 spores/ m^3 in 2001 to AM 0.04×10^6 spores/ m^3 GM (GSD) 0.02×10^6 spores/ m^3 (3.3) in 2009 (Faerden *et al.*, 2014). This was believed to be

Fig. 2 Process overview from forestry to timber production at sawmills. The review of fungi related to sawmills is defined to the work processes at sawmills. Arrows show the process direction and arrows with a greater thickness indicated the parts that are most common. Adapted from Straumfors, A., Foss, O.A.H., Fuss, J., *et al.*, 2019. The inhalable mycobiome of sawmill workers: Exposure characterization and diversity. *Applied and Environmental Microbiology* 85.

Abbreviation: AM, arithmetic mean; EIA, enzyme immunosorbent assay; GM, Geometric mean; GSD, Geometric standard deviation; IG-FESEM, Immunogold Field emission scanning electron microscope (SEM); (IQR), Inter quartile range; LAL, Lumulus Amebocyte lysate assay; OUT, operational taxonomic unit; SEM, Scanning electron microscopy.

due to modernization and major improvements at different stages of the wood processing line to prevent fungal exposure among sawmill workers since the 1980. Straumfors and colleagues recently showed that both inhalable and thoracic fungal exposure among sawmill workers at 11 Norwegian sawmill today were GM (GSD) 0.4×10^5 spores/m³ (3.8–4.4) (Straumfors *et al.*, 2018), i.e., at the same level as Færden *et al.* reported in 2009. This indicates that the declining trend have stagnated after about $200 \times$ reduction over 30 years.

Fungal Fragments – A Large Part of Fungal Aerosol in Sawmills

In spite of the reduced spore exposure over the years, the health risk associated with fungal exposure at sawmills is still of great concern. The use of a novel immunogold labeling method for FESEM where fungal fragments were gold-labeled and counted in a complex environmental sample matrix (Afanou *et al.*, 2015a) recently revealed that the fungal aerosols consists of fragments of various size and shape in addition to spores (Afanou *et al.*, 2015b). The fungal aerosol in sawmills was dominated by large fungal fragments (Afanou *et al.*, 2018). Fragments in the sub-micrometer size were also detected (AM: 0.6×10^5 per m³) in addition to larger fragments (AM: 3×10^5 per m³) and spores (AM: 1.4×10^5 per m³) (Table 1; Fig. 3). This indicates that the fungal aerosol exposure is underestimated by spore counts, but may be included in cultivation if the fragments are viable. The quantification of fragments has not been included in fungal exposure measurements in sawmills previously, and hence not their specific association with health effects. The contribution of fragments in the development of occupational diseases related to fungal exposure is therefore still not known, and need to be clarified in the future.

Revelation of the Sawmill Mycobiome by Metabarcoding

Although SEM can reveal detailed characteristics of surface morphology, shape and size, the identification of airborne fungal particle to species level is difficult. In contrast, DNA-based methods are more robust in targeting all fungal particle types having DNA; viable or dead spores, hyphae and fragments. Molecular methods based on DNA provide a comprehensive approach for fungal identification with chosen level of specificity. Although DNA based assessment of fungal exposure in indoor and various workplaces has been reported (Viegas *et al.*, 2016; Vesper, 2011; Adams *et al.*, 2013), this approach has not been used to the best of our knowledge, in fungal exposure assessment in sawmills until recently. High throughput sequencing (HTS)-based DNA metabarcoding-technology are gaining wide acceptance to capture the complete composition of microbial communities in different environments, including air samples with different size fractions (Cao *et al.*, 2014; Adams *et al.*, 2015; Bartram *et al.*, 2011; Lindahl *et al.*, 2013). DNA metabarcoding of the fungal ITS2 region recently revealed the complete spectrum of inhalable fungi in sawmills, showing a much broader and complex fungal profile than previously known (Straumfors *et al.*, 2019). The most common orders detected among the ascomycetes were the Capnodiales (3.3% of the OTUs and 13.2% of the reads), Eurotiales (1.1% of the OTUs and 9.3% of the reads), Saccharomycetales (1.7% OTUs and 6.8% reads) and Microascales (0.5% OTUs and 6% reads), whereas Tremellales (3.4% OTUs and 6.9% reads), Sporidiobolales (1.2% OTUs and 3.6% reads), Polyporales (4.9% OTUs and 3.4% reads) and Cystofilobasidiales (1% OTUs and 2.8% reads) were most common among basidiomycetes. Among the most abundant species regardless of phyla were the human pathogens *Candida* spp. (Ascomycete) and *Cryptococcus* spp. (Basidiomycete). The second most abundant order, Eurotiales, includes species such as *Aspergillus fumigatus* and *Paecilomyces variotii* that previously were detected as dominating species by cultivation, but these species were detected in very low abundances by metabarcoding. Logs were debarked in an automated station before entering the sawmills, and according to Cormier *et al.*, may *Paecilomyces* and *Trichoderma* primarily occur in the bark (Cormier *et al.*, 2000), which may explain the low prevalence. However, relatively high prevalence of *Rhizopus microsporus* and *Mucor* spp. was detected, which is in line with some of the previous studies detecting these species by SEM and cultivation (Dutkiewicz *et al.*, 2001a; Eduard *et al.*, 1992b). Although the most common order among the Zygomycetes was Mucorales, where these species belong, the abundance of Zygomycetes was in general very low compared to ascomycetes and basidiomycetes. The prevalence and relative abundance of the allergenic *Alternaria alternata* was moderate. Overall, the fungal composition differed significantly across sawmills, departments, wood types and seasons.

Bioactive Fungal Components in Sawmill Aerosol

Fungal exposure measurements includes also the detection of fungal antigens, allergens, toxins and β -1,3-glucans. These bioactive fungal components may all elicit or modulate a response upon inhalation of fungal aerosols, and some of them have been used as markers of fungi in many settings (Madsen *et al.*, 2009; Halstensen *et al.*, 2007). In sawmills Alwis *et al.* measured β -1,3-glucan in respirable (AM: 0.4 ng/m³) and inhalable (AM: 3.28 ng/m³) dust, and found an association between this fungal derived β -1,3-glucan exposure and airways symptoms reported by workers in sawmills processing eucalyptus in Australia (Alwis *et al.*, 1999). Similarly, β -1,3-glucan levels ranging between 0.40 and 92.5 μ g/m³ were reported in the inhalable fraction of dust collected in sawmills in New Zealand, and although no direct cause-and-effect relationship were established, the exposure levels of endotoxin and beta-glucans were sufficient to potentially contribute to the observed symptoms (Douwes *et al.*, 2000). From settled dust collected in sawmills processing hardwood in Croatia, Prester and Macan reported the presence of Asp f 1 allergen (range: <LOD (3.6 ng/g dust) – 120 ng/g dusts) (Prester and Macan, 2014) but not the Alt a1 allergen (<LOD(120 ng/g dust)) (Prester *et al.*, 2010).

Mycotoxins, as being secondary metabolites of fungi, are inherently associated with fungi, and may exert a wide range of toxic effects in mammals. Mycotoxins have been recognized as part of the occupational exposure in moldy work environments such as grain industry and other agricultural industries (Straumfors *et al.*, 2015; Viegas *et al.*, 2018). In spite of the importance of fungi recognized in sawmills, only two reports of mycotoxins in sawmills have, to our knowledge, been published (Land *et al.*, 1987; Land *et al.*, 1993). Isolates of *A. fumigatus* collected from kiln dryers at Swedish sawmills were shown to be producers of verruculogen and fumitremorgin C, that exerted mild to strong tremorgenic effect in rats (Land *et al.*, 1987). Thirty-two percent of *A. fumigatus* strains isolated from 21 sawmills were tremorgen-producers, and the toxins were detected in variable concentrations in the conidia of 7 strains. However, no mycotoxin was detected isolates from different kinds of wood substrates, such as pine, spruce, birch, dried versus non-dried wood, bark, leached wood and wood after various sterilization methods (Land *et al.*, 1993). Although the presence of fungi capable of producing mycotoxins under particular conditions were detected in sawmills suggests that sawmill workers may inhale mycotoxins, the possible role of mycotoxins in HP or other health effects of sawmill workers have not been further studied.

Overall, independent of the method used, large variances between fungal exposure measurements have been observed. An occupational exposure limit (OEL) of 1×10^5 spores m^{-3} has been proposed based on experimental and epidemiological evidence of the lowest observed effect level (LOEL) for exposure to general fungal spores (Eduard, 2009). Although one cannot expect to remove all fungal exposure in sawmills, the industry need to continue improvements of technology and practices that contributes to keep the exposure as low as possible.

Sawmills as Potential Reservoirs of Azole Resistant Fungi

Emerging azole-resistant fungi caused by environmental selection pressure related to the use of azole fungicides in agriculture and floriculture have been described recently (Vermeulen *et al.*, 2013; Verweij *et al.*, 2013; Schoustra *et al.*, 2019). Sawmills also use azole-containing fungicides for impregnation and other wood preservatives, and may as such represent a potential source of pressure for the emerging azole-resistant fungi. Azole-resistant *Aspergillus fumigatus* and *Candida* spp. are of particular concern as

they can cause a wide spectrum of health effects, including invasive aspergillosis (IA) and bloodstream infection, respectively, with high mortality rate (Verweij *et al.*, 2009, 2013; CDC, 2019). Treatment of these opportunistic human pathogens is dependent on azole-containing anti-fungal clinical treatment. Occupational environments may therefore represent a reservoir of potential azole-resistant fungi contributing to the challenges related to the treatment of diseases caused by *A. fumigatus* and *Candida* spp. Azole-resistant *A. fumigatus* with the TR₃₄/L98H mutation has indeed been detected in sawmills (Jeanvoine *et al.*, 2017), whereas resistant *Candida* spp. is, to our knowledge, not reported in this setting.

Determinants of Fungal Exposure in Sawmills

Knowledge of the life cycle of fungi and the conditions at the work place that are favorable for fungal growth and dispersion is of great importance when trying to understand the variability of fungal exposure in both intensity and composition at any work place. Factors related to the work, such as job type, department, raw materials, job organization, and technical installations may influence the personal fungal exposure. The collection of such information during sampling is valuable for identifying whether or not such factors are determinants of exposure. Finding determinants of exposure is valuable for learning about the exposure variations in different occupations, and for identifying where the largest risks are and where potential interventions can be necessary in order to reduce exposure and improve the workers' health.

Wood Type

The most commonly used wood types that are cut and processed at sawmills are spruce (*Picea abies*) pine (*Pinus sylvestris*) and fir (Douglas fir, *Pseudotsuga menziesii*), but in Australia and some African countries, also Eucalyptus are being processed. These wood types are often used in large building constructions, whereas beech, oak and ash are used more in house interiors. Several types of trees, including spruce and pine, have natural resistance against microorganisms (Pearce, 1996; Straumfors *et al.*, 2019). Nevertheless, the wood type may be a determinant of fungal exposure, as reported in Polish and Norwegian sawmills, where the fungal exposure was highest when working with spruce compared with pine (Straumfors *et al.*, 2020; Dutkiewicz *et al.*, 2001a). It was speculated that spruce may be more prone to fungal infection in warm and humid conditions than pine, but different ways of handling and processing various wood types based on their characteristics, may also contribute to differences in fungal exposure. A study of the inhalable mycobiome of sawmill workers revealed that the workers were exposed to significantly different proportions of several fungal genera depending on the wood type they were handling (Straumfors *et al.*, 2019; Fig. 4). The overall fungal composition of the exposure was, however, only slightly affected by the wood type processed in the sawmills. Higher fungal richness was also observed during work with spruce compared with pine, but the average OTU-richness per sample was not significantly different between the two wood types, suggesting that the difference may be due to factors in the sawmills that are not related to the wood types. Whereas the exposure to fungi in the phyla Ascomycota versus Basidiomycota were similar when working with spruce or pine, the relative proportion of Basidiomycota was higher when working with both wood types, suggesting either alternative work organization or different competition in dispersal or growth among fungi when mixed wood types are handled at the sawmills. The differences in diversity (Shannon, not richness), evenness and top 10 OTU abundance between sawmills, suggest that other sawmill specific conditions than different wood types indeed play a role (Straumfors *et al.*, 2019).

Departments

Although the process line in all sawmills are relatively similarly organized, with a green side before drying of the timber and a dry side after drying of the timber, the place of highest exposure has deviated somewhat between studies. Work in the saw and with sorting of green timber have been shown to represent the highest fungal exposure in Norwegian sawmills (Straumfors *et al.*, 2018). Work with sorting of green timber also resulted in significantly higher levels of fungal fragments, compared with the other departments (Afanou *et al.*, 2018). The saw department and the sorting of dry timber departments were by mixed effect modeling shown to give the highest fungal spore exposure intensity. More detailed task-based models showed furthermore that controlling the saw in the planing department and cleaning in the sorting of dry timber department were associated with higher spore exposure estimates than the other tasks (Straumfors *et al.*, 2020). In a Swiss study, sorting tasks were shown to represent significantly higher exposure to fungi compared to planing, debarking and saw tasks grouped together, despite the small number of samples per site (Oppliger *et al.*, 2005). Debarking has previously been identified as an activity with the highest microbial exposure (Duchaine *et al.*, 2000b), but this work is nowadays fully automated in some sawmills, and although there may be high levels of airborne fungi during this process, it will not represent any exposure risk at normal process operations, as no operator will be present. DNA metabarcoding of the ITS2 region of inhalable mycobiome in sawmills has revealed distinct fungal compositional profiles between departments across companies (Straumfors *et al.*, 2019), which is in agreement with a previous study that used cultivation as fungal detection method (Dutkiewicz *et al.*, 2001a). This indicates that workers in different job groups not only are exposed to different levels of airborne fungi, but also to different fungal compositional profiles depending on the department and the sawmill (Fig. 4). A systematic turnover of fungal diversity was observed throughout the process line from dominating orders of *Saccharomycetales* in the saw, *Saccharomycetales* and *Eurotiales* in the sorting of green timber department, *Eurotiales*, *Tremellales*, and *Capnodiales* in the planing department, and *Eurotiales* and *Tremellales* in the

sorting of dry timber department. The fungal composition in the sorting of green timber department were almost completely overlapping with the saw, both being “green” departments where the timber has not been dried yet. Logs entering the saw are newly debarked, and thus are expected to bring along and release microorganisms related to the bark and the external natural environment. While some of this seemed to carry through to the sorting of green timber, other species also were detected. Although it has not been shown that the community composition in heart wood and sapwood of *Picea abies* and *Pinus sylvestris* is different (Leonhardt *et al.*, 2019), fungi growing inside the wood may be released at later stages of the process line. Indeed, the exposure profile of dominating species observed in the sorting of dry timber department and the planer department, respectively, were completely different with no overlap with other departments (Fig. 4). The fungi found here may also have occurred on green timber before being kiln dried, and during storage of dried timber, and thereafter transported on the surface of the timber planks to the sorting department where they were aerosolized.

Seasons

An effect of season on the fungal exposure level may be related to variations in temperatures and relative humidity that will influence the growth conditions for fungi. There could also be conditions at the work place that differs by season, and that will affect the exposure. Considerably higher levels of airborne fungi have been recorded in April-May and July compared with the rest of the year (Klaric *et al.*, 2012). The fungal exposure have been shown to be 2.2 times higher for spores and 2.5 times higher for fragments in summer season compared with winter season (Straumfors *et al.*, 2020). The fungal spore exposure level in a trimming department with relapsing episodes of HP was also higher in winter (4.8×10^6) than in summer (5.3×10^5) (Faerden *et al.*, 2014). Also a higher fungal richness has been observed in summer than in winter, and workers were exposed to different species by season (Straumfors *et al.*, 2019). This is most likely due to more favorable fungal growth conditions and higher rate of spore dispersal in the warm and humid summer season, and in concordance with earlier studies where seasonal differences in fungal communities associated with plant leaves (Davey *et al.*, 2012), roots (Mundra *et al.*, 2015) and soil (Santalahti *et al.*, 2016) were observed. Interestingly, there were systematic seasonal differences in taxonomic composition, with more ascomycetes during winter and more basidiomycetes during summer. This fits into the rough classification of ascomycetes being more tolerant to environmental stress, in this case the harsh winter conditions. Especially many yeast, which are mainly decomposers, were relatively more abundant during winter. This corresponds well with the findings from Santalahti *et al.* showing that saprotrophic fungi, which are metabolically active when photosynthesis conditions are less favorable (Baldrian *et al.*, 2012), dominate during winter compared with the growth season in boreal Scots pine forest (Santalahti *et al.*, 2016). The polypore *Fomitopsis pinicola*, a widespread brown-rot fungus in the boreal forest landscape, was relatively more abundant during summer, when it is expected to be vegetatively more active. However, the abundance of the 10 most common OTU was higher in winter than in summer. This relationship might be related to the evenness of the samples, i.e., if there are fewer species during winter, these will appear as more abundant relatively. Hence, the summer season most likely represents the most diverse fungal exposure. This was also supported by ordination analyzes showing broader ordination configuration of samples collected in summer compared with winter (Fig. 4). Overall, these results highlight that the seasonal shift in fungal communities related to the sawmills may impose variation in occupational exposure.

Other Factors That Impact Fungal Exposures at Sawmills

The type and amount of fungi that colonize the logs in the storage yard will depend on temperature and humidity and the storage time at the particular conditions. i.e., the fungal profile that workers are exposed to is partly be dependent on the fungi that enters the sawmill together with the logs, which again is a result of time and conditions for storage of the logs. Production volume, how much timber is processed per year, may have impact on the fungal presence and the workers exposure. The more timber processed, the higher may the occurrence of natural fungal contamination from the fresh logs become. The persistence of a generally higher fungal level or the growth of particular species at any point along the timber production line, will be dependent on how the sawmill is dimensioned for its production volume and the flow-through time of the timber, i.e., the duration from logs are entering the saw until the cut timber is collected by the costumers. Factors of importance here includes drying and storage capacity, good routines for cleaning sawdust, and exposure reducing measures, such as dust extractors and ventilation. Faerden *et al.* hypothesized that the reduced occurrence and intensity of HP symptoms in trimmers was due to reduction of the outdoor storage time of sawn timber before drying that resulted in less fungal growth on the wood and improved drying process with new kiln (Faerden *et al.*, 2014).

It should be noted that many other non-fungal components of the aerosol at sawmills may cause health effect individually and in combination, and the exposure determinants of the individual components may differ between each exposure component (Straumfors *et al.*, 2020, 2018).

Reducing the Exposure to Fungi

Any action to reduce fungal growth and to reduce the dispersion of fungal particles into the work place aerosol will reduce fungal exposure. Dust extractors and functional ventilation are important exposure reducing measures. However, because each company have their own particular solution of the technological installations, is hard to compare the technological factors between companies in order to identify what is most efficient in exposure reduction. By changing operator position during the shift, workers will even out between them any potential high exposures due to particular tasks. In this respect may job rotation

Fig. 4 Variation in fungal community composition by wood type, season, sawmill and departments. Nonmetric multidimensional scaling (NMDS) ordination analysis of fungal communities in personal air samples from Norwegian sawmills. (a) The plot represents 84 different personal air samples coded by color for the sampling season (summer and winter) and coded by shape for the different wood species (pine, spruce, or a mix of the two wood species) processed on the sampling day. (b) Differently colored ellipses represent the 95% confidence interval around the centroids of individual companies. (c) Differently colored ellipses represent the 95% confidence interval around the centroid for different departments at all sawmills. (d) NMDS ordination analysis showing the fungal operational taxonomic unit (OTU; species) composition from all sawmills. The ordination plot is based on all fungal OTUs present, but only the 30 most common OTUs are shown here. Each of these OTUs represented, on average, at least 0.5% of the total reads. The top 30 OTUs accounted for 49% of the total reads. All factors (season, wood type, sawmill, and department) had significant effects ($P \leq 0.05$) on the ordination configuration. An asterisk denotes a sawmill or department with too few samples for inclusion in the ordination analysis. Rendered from Straumfors, A., Foss, O.A.H., Fuss, J., *et al.*, 2019. The inhalable mycobiome of sawmill workers: Exposure characterization and diversity. *Applied and Environmental Microbiology* 85; Copyright AEM 2019.

contribute to reduce the average exposure during a workday. The use of personal respiratory protection need to be evaluated in particular high-exposure situations and when sufficient exposure reduction is not possible.

Health Effects of Fungal Aerosol Inhalation in Sawmills

Exposure to fungal spores has been associated with HP and other respiratory symptoms among sawmill workers (Wimander and Belin, 1980; Eduard *et al.*, 1992b, 1993; Halpin *et al.*, 1994b; Douwes *et al.*, 2001).

Hypersensitivity Pneumonitis (HP)

HP has, in particular, been reported among sawmill workers handling wood and wood products. Symptoms of and clinical diagnosed cases of HP were previously frequently reported among workers employed in trimming departments of sawmills. A

non-allergic immunological response to the inhalation of *R. microsporus* spores was considered as being the cause. This was confirmed by the presence of serum IgG antibodies against *R. microsporus*, positive precipitating antibodies to the antigens from these species, and recurrent episodes of characteristic symptoms, such as cough, chills fever, 4–8 h after exposure (Faerden *et al.*, 2014). HP has been associated with antigens from *Rhizopus microsporus* (spruce/pine), *Alternaria*, *Aspergillus*, *Trichoderma koningii* (Halpin *et al.*, 1994a), *Thermo actinomyces vulgaris* (moldy wood chip), but also *Cryptostroma corticale* (maple bark) and *Aureobasidium pullulans* (redwood) (Enarson and Chan-Yeung, 1990). Wood trimmers had higher levels of serum IgG towards *Rhizopus microsporus* and *Paecilomyces variotii* than sawmill workers with other tasks with assumed lower fungal exposure (Eduard *et al.*, 1992b). Although the occupational fungal exposure were reduced and the frequency of HP symptoms declined over 9 years, workers still reported HP symptoms several times in a year (Faerden *et al.*, 2014), specifically related to handling of moldy timber.

The validity of exposure estimates in relation to health effects depend on our ability to differentiate between species. This is particularly important when examining specific responses such as allergic asthma, allergic rhinitis and HP. Several of identified species may provoke other immunological and allergic responses, also shown by the presence of specific antibodies in the blood of workers (Cormier *et al.*, 2000; Dutkiewicz *et al.*, 2001b; Eduard *et al.*, 1993).

Many fungal species commonly found in sawmills are sources of allergens, and inducers of IgE-mediated sensitization and causes of atopic respiratory diseases such as rhinitis and asthma. However, IgE mediated reactions to inhaled fungi does not seem to be common in sawmills, but rather a non-atopic, neutrophilic inflammation. In a Croatian study, only one of 96 sawmill workers had positive skin prick reaction to *Rhizopus nigricans*, whereas the reaction towards *Cladosporium herbarum*, *Alternaria alternata*, *Aspergillus niger*, and *Penicillium notatum* were negative for all (Klaric *et al.*, 2012). Rydjord *et al.* detected increased level of *R. microsporus* specific serum IgG in sawmill workers, particularly trimmers, and a decreased level of IgE compared with controls (Rydjord *et al.*, 2007). In a study of sawmill workers reaction to work-related airborne allergens, Dutkiewicz *et al.* observed an association with work-related symptoms and positive immunological response only in for a limited number of allergens tested, including fungi (Dutkiewicz *et al.*, 2001b). Atopy is present among wood workers in similar proportions to the general population (Klaric *et al.*, 2012).

Cedar sawmill workers have higher reported prevalence of asthma compared to a reference population, but fungi is not believed to be the main causal agent for this. On the contrary, Western red cedar (*Thuja plicata*) is regarded mold-resistant, and no cases of HP has been reported after handling this wood type (Enarson and Chan-Yeung, 1990).

Other Inflammatory Airway Responses Among Sawmill Workers

Airway inflammation is commonly induced by constituents of microorganisms. Although microbial species may have different toxicity, the importance of species identification is less obvious for “non-specific” responses such as inflammation of the airways, non-allergic asthma, bronchitis and organic dust toxic syndrome (ODTS), also called inhalation fever. Organic dust toxic syndrome (ODTS) is caused by high dose exposures to fungal spores in moldy materials in several occupations, including sawmills (Sorenson *et al.*, 1998; Rask-Andersen *et al.*, 1994; Enarson and Chan-Yeung, 1990), but can also be induced by bacteria, endotoxins and mycotoxins.

Workers exposed to wood dust showed evidence of chronic airway obstruction, but no unspecific bronchial hyperreactivity when compared with controls (Enarson and Chan-Yeung, 1990). The causal agent for this is not clarified, but seemed to vary with the dust content. Dahlqvist and colleagues reported a mild obstructive lung function deterioration in Swedish wood trimmers exposed to up to 10^6 cfu/m³ compared with other sawmill workers exposed to several times less fungi (Dahlqvist *et al.*, 1992; Dahlqvist and Ulfvarson, 1994).

Chronic bronchitis is shown to be more prevalent in sawmill workers than among grain handlers, with an additive effect of tobacco smoking, but reversible upon cessation of exposure (Enarson and Chan-Yeung, 1990). Although signs of low intensity alveolar inflammation were observed in wood trimmers exposed to low concentrations of dust, fungi and bacteria (Johard *et al.*, 1992), significant differences has not always been observed between exposed sawmill workers and controls (Cormier *et al.*, 2000). Cormier and colleagues showed that overall, sawmill workers with low exposure levels had little or no evidence of respiratory health problems related to their work environment.

Other symptoms, such as irritation of the eyes (burning, itchiness, and lacrimation) or nose (sneezing, itchiness, and rhinorrhea) is usual among sawmill workers, but can be related to nuisance dust, several components of the dust and not necessarily only related to fungal exposure (Demers *et al.*, 1997). As dust contains multiple components potentially affecting the health, it is important to take into account health effects of all components. Very few studies have been designed to evaluate individual and combined effects of the mixed exposure at sawmills.

β -1,3-glucans are glucose polymers with variable molecular weight and degree of branching (Williams, 1997) that are cell wall components of most fungal families, including human pathogens such as *Candida* and *Aspergillus*, but not Zygomycetes. β -1,3-glucans are also produced by algae (laminarin), bacteria (curdlan), and plants (callose), and elicit potent biological responses across several kingdoms, including plants, insects, and animals (Jacobs *et al.*, 2003; Brown *et al.*, 2003). In humans, β -1,3-glucans can induce inflammation or modify concomitant biological responses to endotoxins or allergens by either enhancing or inhibiting their effects (Young and Castranova, 2005). Working in New Zealand pine sawmills has been associated with an increased prevalence of cough symptoms, and eye and nose irritation (Douwes *et al.*, 2001). The causal agent was not clear, as shown by a poor dose-response relationship to dust exposure, but exposure levels of endotoxin and beta-glucans were sufficient to potentially contribute to the observed symptoms (Douwes *et al.*, 2000). The authors stressed that other causal agents such as resin acids, terpenes and other microbial components could contribute, and ought to be included in exposure assessments.

Immune Modulating or Positive Effects of Fungal Diversity

Protective effects associated with fungal exposure have also been reported (Ege *et al.*, 2011; Stein *et al.*, 2016), and it is increasingly recognized that it is the fungal compositional distribution in the exposure that is important to health (von Mutius, 2007; Jatzlauk *et al.*, 2017; Ege *et al.*, 2011; Stein *et al.*, 2016; Haahtela *et al.*, 2015; von Hertzen *et al.*, 2011). The idea is that a rich diversity will modulate all potential effects and reflect a balanced mycobiome, rather than a particular species composition that is beneficial. An imbalance between natural species may cause dominance of few particular species including pathogens that may result in negative health effects. The immune modulating effect of β -1,3-glucans may be part of this balance.

Conclusions and Future Perspectives

There will always be a potential for exposure to aerosols containing fungal particles at sawmills, since wood is natural substrate for many fungi. Sawmill workers were exposed to up to 10^7 spores/m³ in the 80s, but this have been reduced over 200 times over the past 30 years due to improved drying technology and other exposure reducing measures in the sawmill industry. Concomitantly has the frequency and severity of reported HP been reduced, but is still reported several times a year for some workers, and ODS and other inflammatory and respiratory impairments are frequently observed. Recent studies have shown that the fungal exposure at sawmills have a broad species diversity, and consists primarily of fungal fragments. Additionally is the fungal exposure level and composition shown to differ between seasons, wood types, continents and departments. The use of exposure determinants may be useful for evaluating the potential health effects and exposure reducing measures. The presence of resin acids, bacteria and terpenes that individually or in combination may exert health effects complicates the exposure picture further, also because exposure determinants differ between individual components. The evaluation of health effects from this complex fungal exposure challenges the previous perception of causal agents, revealing the need for continuing investigations of how sawmill workers health is affected by fungal exposure. Particularly should the contribution of fungal fragments to health effects be addressed. Further studies are needed to determine factors that shapes the fungal diversity in sawmills, and to elucidate how the differences in the complete fungal spectra relate to health effects, in order to become able to apply the new knowledge for improving workers health.

Next-Generation Sequencing in Environmental Mycology. A Useful Tool?

Hamza Mbareche, Sunnybrook Research Institute, Toronto, ON, Canada and University of Toronto, Toronto, ON, Canada

© 2021 Elsevier Inc. All rights reserved.

Introduction

Since the rapid development of next-generation sequencing, more commonly referred to as high-throughput sequencing (HTS) methods in the recent years, fungi have been the underdogs of the microbial world, especially in bioaerosol studies. Particularly, studies describing fungal exposure in different occupational environments have been limited by traditional culture methods that underestimate the broad spectrum of fungi present in the air (Peccia and Hernandez, 2006). There are potential risks in the human inhalation of fungal spores in an occupational scenario where the quantity and diversity of fungi is high (Shams-Ghahfarokhi *et al.*, 2014; Ekhaïse and Ighosewe, 2008; Douglas *et al.*, 2018). Although some health problems are already known to be associated with fungal exposure in certain work environments, the risk may be underestimated due to the methods used (Fabian *et al.*, 2005; Peccia and Hernandez, 2006). The presence of previously undocumented fungi in aerosol samples represents one of the limitations in the understanding of the impacts of fungal exposure on respiratory health (Bush *et al.*, 2006; Tischer and Heinrich, 2013). The harmfulness of fungal aerosol mixes could be dependent upon the composition of elements, synergy among the elements, and factors attributable to source and growth conditions (Fröhlich-Nowoisky *et al.*, 2016; Aleksic *et al.*, 2017). The absence of a universal method to explore fungal exposure in occupational settings is not surprising due to the limitations of the actual methods. To date, many questions are still unanswered in the use of molecular methods to characterize the fungal diversity of aerosols. The hypothesis is that, although essential in the study of biodiversity, traditional approaches based on the cultivation of fungi induce a bias in the representation of fungi in aerosols (Fabian *et al.*, 2005; Peccia and Hernandez, 2006). Thus, a method based on HTS with the appropriate barcode could be optimal to reveal the diversity of fungal aerosols and to provide exposure data with a maximally complete image of the presence of fungi (Tedersoo *et al.*, 2015, 2018). For example, applying HTS in soil samples has helped the explanation of the fungal role in many other ecosystems (Nilsson *et al.*, 2019a,b). Nonetheless, the literature is still not decisive in terms of the genomic region to use as target for the enrichment and sequencing of fungi (Tedersoo *et al.*, 2015; Wang *et al.*, 2014). The motivation behind writing this chapter is the desire to introduce an overview of new approaches to study fungal aerosols. The reason behind this motivation was to compensate the gaps caused by the traditional approaches used in the study of fungal exposure in occupational environments. The traditional methods consist of cultivating fungal species collected from air samples to study their concentration and diversity. The gap in the literature caused by the application of cultivation methods solely is linked to the specific representation of the cultivable and viable portion of fungal aerosols. The underrepresented portion of the fungal community might have a significant role in the adverse health effects related to exposure. Thus, it is necessary to consider not only the tip of the iceberg, but also look at the bigger picture of fungal aerosols. The willingness to fill the gap of the occupational studies with the non-viable or the uncultivable portion of fungal aerosols took us to consider the application of molecular tools. These tools, amongst others, consist of HTS of the genomic DNA extracted from aerosol samples taken from environmental settings, as streamlined by targeting various fungal universal barcodes. In addition, culturomics, which consists of the application of multiple culture conditions, combined with amplification and sequencing for the identification of previously unidentified colonies, is also mentioned for its ability to offer complementary images of fungal diversity identified by molecular tools (Amrane *et al.*, 2018). Also, with HTS becoming more popular, more bioinformatic tools are available, and choosing the right tool is a prerequisite to a valid diversity analysis. The author was also motivated by the desire to present an overview of the bioinformatic tools available that can offer the readers the freedom to control every step and parameter in the process of sequence treatment and diversity analyses.

Environmental Exposure to Fungi

From an occupational health perspective, enhancing our understanding of the risks related to exposure requires attention. The relevance of bioaerosol data is needed for risk assessment and risk management (Mbareche *et al.*, 2019a,b,c). Industrial and agricultural environments are the major considerable concerns in occupational health issues due to the presence of potential fungal sources (e.g., raw organic materials), and the occurrence of operations releasing harmful bioaerosols (e.g., mechanical operations such as wood planning, straw chopping, animal bedding, hay handling, and compost pile turning). The generation of large amounts of bioaerosols in confined spaces is what make this type of exposure of importance in occupational health. Bio-waste facilities are characterized by notable concentrations of fungal aerosols due to the fungal activity responsible of the waste degradation and the daily activities related to composting (Wéry, 2014; Bonifait *et al.*, 2017; Dubuis *et al.*, 2017; Mbareche *et al.*, 2017). Intensive animal farming practices in confined buildings containing many animals (e.g., cows, pigs, poultry, cattle) are also associated with extreme exposure to airborne microbes. The variety of possible sources (e.g., animals, feces, feed, litter) present at farms leads to the emission of complex mixtures of biological particles (Gilbert and Duchaine, 2009; Lanier *et al.*, 2010; Létourneau *et al.*, 2010; Tsapko *et al.*, 2011; Douglas *et al.*, 2018). Moreover, the constantly changing nature of the microbial composition over time and space makes health risk evaluation complicated for farm workers and nearby residents (Iversen *et al.*,

2000; Schiffman *et al.*, 2005). Environmental scientists, public health practitioners, and epidemiologists continue to insist that insufficient exposure assessments are one of the main reasons for the absence of bioaerosol exposure limits and strategies to mitigate risk (Douglas *et al.*, 2018; Walser *et al.*, 2015; Mubareka *et al.*, 2019).

Studies in occupational health are pointing toward adverse health effect, especially respiratory symptoms, among workers exposed to high levels of fungal aerosols (Gilbert and Duchaine, 2009; Douglas *et al.*, 2018). Health-related exposure limits are crucially needed for implementing procedures to decrease workers' exposure to an acceptable level. This field of bioaerosols could make great progress by using suitable measurable parameters, developing standardized detection methods for exposure markers, combining different detection methods to compensate the limitations of different approaches, and applying new analysis methods to identify the potential hazard incurred by workers in different occupational settings. As stated by Mubareka *et al.* (2019), the field of applied bioaerosol research can benefit from having an open network research (collaboration of different specialists); a shared technical protocol and training programs; engaging knowledge users; enhancing capacity-building for response measures (development of best practices). Particularly for fungi, culture methods have been the golden standard for all the training programs and the build-up knowledge on fungal concentrations, and taxonomy in different environments.

Cultivating Fungi

Although HTS methods are increasing the possibility for fungal studies, data production from cultivating fungi cannot be underestimated. Isolation of fungal species is essential to understanding and studying phenotypic and genotypic characteristics of single isolates and to better assess biodiversity. Antifungal resistance is a current trend that represents a major clinical challenge for treating invasive fungal infections (Wiederhold, 2017). Like for bacteria, clinicians are facing the limited stock of available antifungal agents. Antifungal resistance has been found in species of *Candida albicans*, *Aspergillus fumigatus*, *Scedosporium*, and *Fusarium* worldwide (Wiederhold, 2017). Even if using molecular methods allow the identification of resistance genes, cultivating fungi carrying the gene of interest is key for the determination of antifungal resistance phenotypes. Furthermore, culture methods provide the link between antifungal resistance measured in the environment, and antifungal resistance detected in human clinical specimens. In addition, cultivation of fungi inform on the antifungal concentrations range, which is an important factor in invasive fungal infections treatments. In sum, both molecular and cultivation methods are needed to get the full spectrum of resistomes. Another example of the advantages of cultivating fungi is the intracellular parasites, microbes that are capable of growing and reproducing inside a host cell. Some fungal intracellular parasites include *Histoplasma capsulatum* and *Cryptococcus neoformans* (Sebghati *et al.*, 2000; Feldmesser *et al.*, 2000). Efforts in associating optimized culture conditions, and detection methods allowed a better understanding of the mechanisms used by intracellular pathogens (Orfila, 1996). In general, subjects with a T cell deficiency are particularly affected by intracellular pathogens (Carneiro-Sampaio and Coutinho, 2007). One common example, more related to occupational exposure, of the importance of cultivating fungi is the production and characterization of antibodies to environmentally important fungal species. It's a technique that has been used to describe exposure and workers' susceptibility to fungi in different workplaces (Eduard, 2009). Finally, even some molecular techniques require the cultivation of fungi. Reverse Sample Genome Probing (RSGP) is a method used to analyze microbial composition of the most dominant culturable fungal species by using genome microarrays. One of the steps of the RSGP is the isolation of genomic DNA from pure cultures (Voordouw *et al.*, 1991).

Now that the conviction is undeniable that a pure fungal culture remains essential for the reasons cited above, cultivating fungi in diversity studies is problematic. Indeed, most fungal species are difficult to isolate using common culture methods. Growth media and conditions are not known for most fungi. The ones that are used commonly (Sabouraud and Rose-Dextrose Agar; Malt Extract Agar) may advantage some species and be less fit for others. The bias could create an imbalance in the fungal species represented in bioaerosols. In particular, considering that the fungal kingdom is one of the most diverse one (Blackwell, 2011). Viability is not the only condition fungi can cause harm once inhaled. Cultivating airborne fungi for concentration measures and diversity analyses is still current amongst bioaerosol researchers. Distinctly, exposure to bioaerosols in waste work environments has received a particular attention for the use of culture methods. In a 2016 study, Madsen and collaborators have identified 23 fungal species, and a total concentration of fungi up to 4.6×10^4 fungi m^{-3} inside the truck cap during waste collection (Madsen *et al.*, 2016). A more recent study of 2018 has set to evaluate the risk of occupational exposure to viable fungi in five waste-sorting industries, identifying a total of 13 different species with a mean count of 1.6×10^4 total fungi m^{-3} (Santos *et al.*, 2018). In beginning of 2019, Madsen and collaborators identified 21 different fungal species with a personal exposure of 6.5×10^4 CFU m^{-3} in cardboard waste sorting facilities. Outdoor environments are also still characterized using culture methods. In 2016, a fungal exposure analyses in various outdoor settings identified 18 different fungal species, with *Cladosporium*, *Penicillium*, *Aspergillus*, *Alternaria*, and *Rhizopus* being the most abundant (Ghiesan *et al.*, 2017). Also in 2018, a study monitoring airborne fungi in different outdoor spaces has identified *Aspergillus*, *Penicillium*, and *Cladosporium* as the dominant genera (Ziaee *et al.*, 2018). In addition, a thesis from the University of Iowa, published in 2018 as well, described cultivable airborne fungal concentrations and diversity in 100 different indoor and outdoor locations registering different climates of the United States. The study identified close to 40 fungal species (Messer, 2018). Indoor studies are also familiar with the use of culture methods for the assessment of cultivable airborne fungi (Liu *et al.*, 2018). A recent review of common indoor fungi has identified *Aspergillus*, *Penicillium*, *Cladosporium*, *Alternaria*, and *Fusarium* as the major fungi in hospital interior environments (Marques do Nascimento *et al.*, 2019). A survey of 71 classrooms has also used cultivation methods to address schoolchildren indoor exposure to fungi (Madureira *et al.*, 2018).

A rookie in the -omics team (metagenomics, metatranscriptomics, metabolomics, etc.), which is a part of the culture methods family, appeared in recent years as a promising new technique in microbiology. As indicated in the name, culturomics consists of the application of high-throughput culture conditions combined to 16S rRNA amplification and sequencing or matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) for the identification of previously unidentified colonies. Although the first mention goes back to 2012, culturomics gained popularity in recent years (Lagier *et al.*, 2012, 2015, 2016; Amrane *et al.*, 2018; Kambouris *et al.*, 2018; Hosny *et al.*, 2019). Most of the studies using culturomics were done to explore the gut microbiota, with a focus on bacterial communities. Future efforts in culturomics could include fungi, as the actual knowledge on high-throughput culture conditions of fungi is very limited compared to bacteria. For fungi, studies combining culturomics and HTS in human gut have arrived to the same conclusions about the complementarity of both approaches in describing fungal diversity of the gut (Hamad *et al.*, 2017). Fungal bioaerosol studies can benefit from the complementarity of these approaches to better understand exposure and its impact on health.

In consideration of the complexity and the diversity of fungi in different ecosystems, one would expect such diversity to be mirrored in bioaerosols too. Yet, occupational, indoor and outdoor bioaerosol studies characterizing fungal exposure around the world refers to the same major key players in the fungal kingdom, as demonstrated above. Could it be that the underdogs of the fungal kingdom are awaiting to be put on the spotlight by applying the right methods? Shade and his collaborators have demonstrated brilliantly the complementarity of culture-dependent and culture-independent approaches to studying bacterial diversity in soils. The premise of their study is that culture-dependent methods reveal bacteria from the rare biosphere and provide supplemental information to that obtained using a HTS approach. The latter method would be beneficial for the most abundant taxa. This brings the hypothesis that all these years microbiologist have been studying the rare biosphere (Shade *et al.*, 2012). Thus, combining culture-based methods with HTS can provide a richer portrait of microbial diversity than does either approach alone. Airborne fungi in different environments and conditions deserve the same attention to better understand, not only the ecological importance of fungi in the air, but also to validate the members contributing to the adverse health effects of being exposed to them.

To sum up, cultivating fungi alone underrepresent the extent of airborne fungal diversity and their exposure in occupational settings. As mentioned previously in this chapter, the application of HTS methods will provide us with necessary information in order to complete the portrait of fungal diversity.

High-Throughput Sequencing

The use of molecular methods in microbial studies is based on the detection of genetic material of organisms present in a given sample. Applying these methods to different environments permitted the identification of the microorganisms present, and a better comprehension of the environmental impacts and ecological roles of microbial communities (Venter *et al.*, 2004; Delmont *et al.*, 2011; Walter and Ley, 2011; Philippot *et al.*, 2013). The countervailing approach of molecular biology to culture methods can be appreciated in the representation of the non-viable or the uncultivable (unknown culture conditions) portion of microbes, extending the measurement to a total biomass (uncultured + cultured). In addition, it became a common knowledge that only a few percentage (less than 1%) of microbes can be recovered by enrichment culture. Although it was first demonstrated for bacteria from soil and aquatic environments (Amann *et al.*, 1995; Pace, 1997), other studies, measuring both total and culturable microbes, showed the same tendency for bacteria and fungi in bioaerosols (Peccia and Hernandez, 2006). For example, in 2005, Fabian and collaborators showed that the percentage of culturability in outdoor air was 0.1% for bacteria (trypticase soy agar), and 0.001% for fungi (malt extract agar; Fabian *et al.*, 2005). Without a doubt, the reliance on culturing alone is a limitation in bioaerosol studies.

Molecular methods do not assess organisms viability or integrity. However, some negative health impacts, like allergies, do not rely exclusively on the viability of microbes. The enormous potential of molecular biology methods for describing bioaerosols, expanding the diversity of microbes that can be detected, identified, and quantified counterweight the critics. Other major challenges are associated with the detection of nucleic acid to identify and quantify microbes, and they can be summarized as follows: (1) concentrating and retrieving the biological material from aerosol samples prior to analyses; (2) choosing the right genomic regions to amplify and/or to sequence in order to obtain the most accurate information about the microbial content of the environment sampled. Specific genes from different organisms can be detected using quantitative real-time amplification (qPCR), which lead to a concentration of specific microbes in air. Virulence factors genes, metabolic operons or antibiotic resistance genes can also be quantified from environmental samples (Chizhikov *et al.*, 2001).

David Stahl developed the concept of molecular microbial ecology based on the sequencing of the 16S rRNA gene region and comparing it with databases (Amann *et al.*, 1990). This concept has been used for the last decades to study microbial diversity in environmental samples. Detection and identification of bacteria can be achieved using the conserved 16S rRNA prokaryotic gene, after centrifugation of liquid or filtered and re-suspended air samples. For fungi, two major challenges are confronted: they are not efficiently recovered from liquid air samples using centrifugation protocols used for bacteria and archaea (Mbareche *et al.*, 2019a,b,c) and the choice of the genomic region to be used that will lead to a representative image of bioaerosols content is difficult. The eukaryotic conserved regions, 18S rRNA gene and ITS regions, can be used depending on the context of the study. Even though those regions have highly conserved functions in their respective organisms, there are some distinct differences between their variability in eukaryotes compared to prokaryotes. For example, while the V6 region in 16S rRNA gene has been considered as variable and well-suited for assessing bacterial diversity (Huse *et al.*, 2008), its equivalent in the 18S rRNA is more conserved in eukaryotes and it is often avoided for that reason (Sogin, 1991; Hadziavdic *et al.*, 2014). The relevance of the ITS region to describe fungal diversity in aerosols will be covered later in the next sub-section.

Although they might not give a direct information on dissemination and transmission of diseases, using molecular approaches to detect DNA sequences from an environment give crucial information. Indeed, they enable us to link aerosol content directly to the source and have a better evaluation of the air contamination. For example, detecting high concentrations of *Aspergillus fumigatus* in a composting environment using qPCR is a good indicator that workers might be at great risk of developing health problems, regardless of the viability of *Aspergillus fumigatus* in our samples. Thus, using HTS approach can give an indication about the most abundant microorganisms in an environment. Then, qPCR can be applied to have a concentration per cubic meter of a specific genus. This will add a biomass indicator to the diversity portrait. Finally, the type of exposure can be investigated in regard to the transmission and the dissemination of microbial agents.

The HTS method was applied to bio-waste and agricultural environments with successful outcomes in the description of a large specter of fungal diversity. The results obtained from composting facilities showed that the fungal composition was dependent on the type of waste treated. The differences between the two types of compost were statistically significant, and were driven by the class of Eurotiomycetes, which were more abundant in carcass and placenta composting, while Sordariomycetes were dominant in domestic composting. Very diverse fungal profiles were obtained for the two types of composting environments, in the compost pile and air samples. Although, the taxonomic profiles showed a clear link between the source and bioaerosols, some taxa of interest were detected in higher proportions in air samples compared to the composting piles. This suggests a higher risk of inhalation by daily exposed workers by these particular fungi (Mbareche *et al.*, 2017). For Biomethanization, the results obtained from the diversity analyses confirmed the relation between the fungal composition and the type of waste treated, previously observed in the compost study, as the taxonomic profiles were different for both facilities. Like the compost environment, a large diversity profile was observed in bioaerosols from both facilities showing the presence of pathogenic fungi. This observation served as a proof of the validity of the approach applied because, it was able to catch the difference in fungal composition of bioaerosols released from both facilities. Plus, quantifying the fungal biomass with qPCR allowed the addition of an absolute quantification, rather than just a relative abundance. The combination of both approaches offers a more complete idea on the type of fungal exposure (Mbareche *et al.*, 2018). Similar methods were applied to air collected from five dairy farms. Concentrations of *Penicillium* and *Aspergillus* reached a maximum value of 10^6 gene m^{-3} of air. The taxonomic profiles obtained from the five dairy farms were different, proving that the method is able to capture important players in the fungal community, and that fungal composition may vary depending on different conditions of each farm. Many opportunistic fungi were identified in air samples of dairy farms, suggesting a potential harm on daily exposed individuals. The intake of culture methods on fungal diversity showed a complementarity of both approaches in the most abundant taxa. In other words, when the most abundant fungi were considered HTS and culture gave complementary taxonomic profiles. However, when all the taxa were considered, HTS undoubtedly outperformed the culture approach in identifying fungi in aerosols from dairy farms.

This paper serves as an endorsement of the methodology applied in terms of fungal analyses in aerosol samples, from the sample treatment to the diversity analyses (Mbareche *et al.*, 2019a,b,c).

High-Throughput Sequencing Platforms

Many commercial HTS platforms have got involve in the sequencing business since the completion of the first draft of the human genome by the traditional Sanger sequencing. As a consequence, the cost of genome sequencing had dropped drastically (Schloss, 2008). The specific paradigm applied by each platform includes sample preparation, amplification (when applied), followed by a massive cycle of parallel sequencing. These steps influence the quality, quantity, and biases of the output sequences, which control the platforms usefulness for specific applications. Since the HTS outbreak, some sequencers have stopped offering services, therefore, they will not be covered in this chapter. Other platforms, although important, are also not mentioned because of their infrequent use in microbial ecology studies. Examples of these cases include, 454 pyrosequencing by 454 Life Sciences, part of Roche Diagnostics; Qiagen-intelligent bio-systems sequencing -by-synthesis by IBS, acquired by Qiagen; Polony sequencing by Polonator; Sequencing-by-ligation by ABI SOLiD; and DNA nanoball sequencing by Complete Genomics, acquired by the Beijing Genomics Institute. Detailed information about the chemistry and sequencing technologies used by these platforms can be found in reviews like the one conducted by Morey *et al.* (2013).

Currently, Illumina platforms dominate the HTS market. The sequencing by synthesis is performed on bridge amplicon obtained by PCR amplification. This type of sequencing consists of the polymerase-catalyzed addition of reverse terminator fluorescent labeled bases. The bases are added simultaneously to the reaction and compete to link with oligo primed cluster fragments. Only one base can be attached in a cycle, preventing other bases of subsequent attach. A coupled-charge device (CCD) camera scans the flow cell capture the image. After each imaging, 3' blocking is chemically removed, and the process is repeated. Illumina have a set of sequencers: MiSeq, NextSeq, and HiSeq optimized for various applications. All Illumina models have an overall error rates below 0.1%, with the most common one being substitutions (Dohm, *et al.*, 2008). The MiSeq is set as a fast, personal benchtop sequencer, with a 4-h run time and designed for amplicon-based sequencing, and also suited for sequencing of small genomes. The HiSeq series were created for application where a deeper sequencing is needed. For example, the HiSeq 2500 gives an output of 1 Tb in 6 days, while the HiSeq X Ten is capable of giving 1.8 Tb in 3 days. Recently, Illumina released the HiSeq 3000/4000 platforms with a run time and an output between the HiSeq 2500 and the HiSeq X Ten (Reuter *et al.*, 2015).

Ion torrent sequencing is another popular platform amongst microbial ecology researchers. Amplification is obtained by emulsion-PCR, similar to 454 pyrosequencing platform. The sequencing is based on a semiconductor where hydrogen ions are

generated and detected after dNTP insertion, rather than by emission of light like Illumina. The detection is performed by a semiconductor chip that measures pH changes induced by the release of hydrogen ions during DNA extension. Ion Torrent Systems wanted to improve sequencing times by omitting the time consumption of imaging steps, which reduces the overall cost. The original benchtop sequencer is Ion PGM with an output capability up to 1 Gb and a speed of runs of 2 h. A second sequencer was released in 2012, the Ion Proton, 10 times more outputs (10 Gb). However, the read length is 200 bp compared to 400 bp for Ion PGM. Ion Proton is more suitable for whole-transcriptome analyses, whereas Ion PGM is suited for targeted sequencing. Recently, a third platform was released under the name of Ion GeneStudio S5, which increased the maximum read length to 600 bp and an output of 1.5–4.5 Gb with a run time of 22 h. Insertions and deletions are the most common error type in Ion Torrent chips, with an error rate of 1%.

There are two other sequencing technologies, although less popular than Illumina and Ion Torrent, that are worth the mention because of their potential overtake over current sequencing technologies in the near future, in the case of particular applications. Pacific Biosciences commercializes the single-molecule real time (SMRT) designed by Nanofluidics. Briefly, a capped DNA template is produced by ligation of a single-stranded hairpin adapter onto the ends of the digested DNA, and by using a strand displacing polymerase, the DNA molecule is sequenced. While polymerization is occurring continuously, the DNA sequence is read in real time with a video recording the fluorescent signals emitted. Each SMRT cell produces 50 k reads (up to 1 Gb) in 4 h, and an average read length of more than 14 kb. But, as with most SMRT, error rate are high (11%), and consist primarily on insertions and deletions. Oxford Nanopore Technologies developed a nanopore based single molecule sequencing platform. In short, DNA is fragmented and adapters are ligated: the first adapter is linked to a motor enzyme and the second is a hairpin oligonucleotide that is linked to a motor protein. The nanopore flow cell contains hundreds of microwells, each comprises a biological nanopore. A molecular motor protein measure the changes of current characteristics induced by the bases passing through the pores. The output is >90 Mbp for an 18 h run time, and a maximum length >60 kb. SMRT sequencing is usually suited for small bacterial and viral whole genome sequencing.

HTS methods were since adapted to study microbial diversity in bulk environmental samples. One of the most used techniques is the targeted sequencing approach, where a specific gene marker is amplified and sequenced with the defining goal of species identification. This method is also referred to as metabarcoding, environmental barcoding, or amplicon sequencing. Basically, this approach changed the field of microbial molecular ecology by targeting whole communities at the same time, instead of isolating individual members. In the particular case of the marker genes, amplicons produced are suitable for phylogenetic analyses, which is important for phylogenetic diversity given the rapid pace of new sequences generated in various environments. The accuracy of the results obtained from the amplicon-based HTS approach is in the gene marker selection. These markers are selected based on their presence across the organisms of interest and having sequence variations between the species. The 16S rRNA gene is the most used gene marker for prokaryotes. However, eukaryotes have many markers options depending on the organisms studied. For example, animals are most studied by targeting the mitochondrial gene COI (Hebert *et al.*, 2003). For plants, the *rbcl* and *matK* has been used as the gene markers in diversity studies (Hollingsworth *et al.*, 2009). For fungi, the ITS region within the rDNA is considered to be the universal fungal gene marker (Roe *et al.*, 2010; Dentinger *et al.*, 2011; Schoch *et al.*, 2012). One particularity of the ITS region is that the sequence length vary between fungal taxa, unlike the length of the 16S rRNA gene used for bacteria, which is similar. For example, in Ascomycota and Basidiomycota the sequence lengths range between 600 and 900 bp (Toju *et al.*, 2012). Amplicon-based HTS approaches involve the amplification of the target gene marker before its sequencing. The most commonly used high-throughput sequencers have a maximum read length limitation. For Illumina MiSeq and HiSeq, maximum sequence length are 2×300 bp, and 2×125 bp, respectively. For Ion torrent Ion PGM, the maximum sequence length is 400 bp. This restriction forces the choice between ITS1 or ITS2 when applying the amplicon-based HTS approach, as the 5.8S gene does not contain a sufficient number of informative sites that can be used to design primers that can be informative for the differentiation between species. The ITS region is composed of three sub-regions: ITS1, 5.8S, and ITS2, and it is an inserted region separating the small ribosomal subunit 18S and the large ribosomal subunit 28S. To the best of our knowledge, there are no relevant studies that explored the potential of both sub-regions in the characterization of fungal communities in bioaerosols. A strategy that is actually being considered for publication is using both subregions, coupled with shotgun metagenomics, to demonstrate their potential and relevancy for a global fungal characterization by coming up with a standardized methodology for the assessment of fungal exposure in occupational settings. The results obtained are unequivocal toward ITS1 outperformance to ITS2 in terms of richness, and taxonomic coverage. The differential abundance analysis did demonstrate that some taxa were exclusively detected only by ITS2, and vice versa for ITS1. However, the shotgun metagenomic approach showed a taxonomic profile more resembling to ITS1 than ITS2. Based on these results, neither of the barcodes evaluated is perfect in terms of distinguishing all species. Using both barcodes offers a broader view of the fungal aerosol population. However, with the actual knowledge, we strongly recommend using ITS1 as a universal fungal barcode for quick general analyses of diversity and when limited financial resources are available, primarily due its ability to capture taxonomic profiles similar to those obtained using the shotgun metagenomic approach (Mbareche *et al.*, 2020).

Another molecular ecology method used to profile microbes is metagenomics. This HTS method involves sequencing of all the genomic material in a sample without a specific target enrichment. Thus, it allows the analyses of mixed communities in environmental samples. Other names for metagenomics are environmental genomics or shotgun sequencing, to differentiate it from amplicon sequencing. An advantage of this approach is the absence of an amplification step prior to DNA sequencing, avoiding in PCR amplification biases or selective primer biases. Because no particular gene is targeted, the functional potential of a sample can be explored, in addition to taxonomic analyses. Also, the metabolic potential of organisms from different environmental samples under different conditions can be compared. Depending on the sequencing depth and the genome size, reconstruction of individual

microbial genomes can be achieved by bioinformatics' *de novo* assembly programs. A recent study published in Nature Microbiology assembled 8000 prokaryote genomes 1500 metagenome sequences available in public databases (Parks *et al.*, 2017). However, fungi do not benefit yet from this achievement as the size of eukaryotic genomes and their complexity make it difficult. Improving sequencing platforms and machine learning assisted bioinformatics may make this possible in the future. In addition, taxonomic assignment may be biased toward microbes with the whole genomes available in the database used.

Due to the fact that not only gene markers are sequenced, other sequenced genes of the genomes may be hard to identify to the species level with confidence. Also, the sequencing depth needed to cover the diversity of an environmental sample is technically higher if the shotgun sequencing is used versus amplicon sequencing. As mentioned above, with HTS and SMRT sequencing technologies advances, the output increases, and the costs decrease. Combined to the attractive advantage of PCR-free, and the continually growing databases of annotated genomes, metagenomics popularity will continue to grow amongst bioaerosol researchers.

Although the sequencing-based approaches described in this chapter are popular and their use is widespread amongst microbial ecology investigators in general, and only recently for bioaerosol specialists, they present key limitations. Certainly, bioaerosol studies applying modern microbial molecular ecology methods should move from descriptive to bringing answers and solutions to decision makers, to ultimately reduce exposure and improve occupational health. This goal can be achieved by continuing the development of standardized laboratory methods, improving bioinformatics algorithms and their usage by scientists, curating more complete and better qualified databases, and combining data from different analyses. A perfect example of data integration is the combination of HTS outputs and culturomics to improve the understanding of microbial communities. Reference databases could use the help of professional taxonomist, whose expertise on isolates identification can enhance the identification of new species. As a consequence, the relative abundance of unidentified taxa will decrease. As amplicon-based HTS approaches depends on database for taxonomic identification, bioaerosol exposure studies applying these approaches could identify a larger number of airborne microbes, and thus, have a closer look to the real diversity of bioaerosols.

In addition to error rates and types associated to each sequencing platform, the high accuracy of homopolymers, and the GC-rich regions amplification problems, short reads lengths produced by most current platforms limit the ability to characterize large regions, with insertions and deletions, and structural variation (Ross *et al.*, 2013). Improvements in the long reads sequencing technologies can help overcome this limitation. Long HTS reads from technologies such as PacBio (see "Relevant Websites section") and Oxford Nanopore (see "Relevant Websites section") are gradually becoming available. To put it in context, one downfall of the actually most used sequencing platforms is the short sequencing reads. For example, we often choose a partial sub-region among the nine variable sub-regions (V1 to V9) of the full 16S rRNA gene so that the chosen region is fully sequenced by Illumina MiSeq (2×300 bp), HiSeq 2500 Illumina (2×125 bp) or Ion PGM (400 pb). With the increasing demand of more accurate methods to analyze microbial communities from different environments, sequencing longer amplicons (e.g., the full-length 16S rRNA gene) is appealing. Primarily, because of its potential to better identify bacteria at the species level. Indeed, the high similarity of the 16S rRNA amplicon sequences usually used with Illumina or Ion Torrent make the accurate species level identification difficult. To overcome this situation, recent microbiome studies have used the nanopore sequencing platform to sequence the full-length 16S rRNA amplicon from the mouse gut microbiota. A comparison of the nanopore (full-length 16 rRNA gene) and short-read (V3 and V4) Illumina sequencing data showed that there were no significant differences in major taxonomic units, with 89% of similarity between the two approaches. Moreover, both sequencing data were highly similar at all taxonomic resolutions except the species level. At the species level, nanopore sequencing allowed identification of more species than short-read sequencing, facilitating the accurate classification of the bacterial community composition (Shin *et al.*, 2016). With these results in mind, applying the same approach to sequence the full-length ITS region represent a compelling avenue for fungal amplicon-based HTS methods, without having to choose between ITS1 or ITS2. However, a proof of concept should be conducted to fine-tune library preparation, including the best set of primers to amplify the ITS region. In addition, UNITE has already started to include long PacBio reads comprising the full ITS region, including few hundreds bases of the LSU gene, to the database (Nilsson *et al.*, 2019a,b).

Like for other environments, fungi in aerosols could benefit from the myriad of methods available to answer questions related to their occupational impact. Amplicon-HTS, shotgun metagenomics, metatranscriptomics, culturomics, and qPCR can all bring insightful information depending on the questions asked. What is the source of fungal bioaerosols? What are the environmental factors favorizing aerosolization of fungi? Who is there? How are they interacting? Is this interaction susceptible to amplify the harm? What is the metabolic potential? Are there any differential expression of genes involved directly or indirectly to fungal pathogenesis? The answers to these questions could take us to answer other types of occupational questions. Is it possible to eliminate the source? How can we reduce the exposure? Can we control the factors favorizing aerosolization? Could the measures proposed change the quality and quantity of fungal exposure?

The success of the combination of multiple methods to study fungi in aerosols reside in the creativity applied to analyze the data. Machine learning is a subset of artificial intelligence based of algorithms and statistical models that computers use to perform specific tasks without a definite instruction for each task (Bishop, 2006). Concretely, the algorithms build mathematical models from a set of training data to predict the next decision without being programmed to do so. In the context of molecular ecology, data mining is the machine learning field of study closely related to the analyses needed for HTS data. Data mining focuses on discovering patterns in large datasets with the use of machine learning, statistics and databases. It allows the exploration of data analyses through unsupervised learning. Supervised machine learning include support-vector machines and it is possible when more data information are available.

Recent work on HTS environmental DNA (eDNA) have showed that machine learning could overcome many limitations of taxonomy-based eDNA bioassessment (Cordier *et al.*, 2018). The algorithms used could predict accurately biotic indices values from

HTS data, regardless of the taxonomic identification of the sequences. In the Cordier study, prokaryotic and eukaryotic ribosomal markers yielded the same accuracy of the predictive models to assess the environmental impact of marine aquaculture. This suggests that the use of predictive models with training datasets from HTS on relevant molecular markers that comprises different potential bioindicator taxa have the potential to overcome some limitations of the traditional methods. Thus, the combination of microbial HTS with machine learning algorithms can be highly effective in filling important gaps of microbial ecology studies. For example, machine learning models were previously used to predict effluent concentration in a wastewater treatment plant (Guo *et al.*, 2015). In addition, microbial community compositions helped the establishment of predictable effluent parameters, like temperature, suspended solids, biochemical oxygen demand, using machine learning's vector regression models (Liu *et al.*, 2016). The application of machine learning to bioaerosols could include scaling-up both spatial and temporal resolution for larger and more ambitious monitoring of exposure. It could be used to predict microbial source tracking, and provide a clearer vision of the environmental impact of bioaerosols.

The challenges related to sequencing technologies can be managed from a bioinformatics point of view. Indeed, bioinformatics analyses can have an impact on diversity analyses such as the clustering algorithms, the percent identity threshold and taxonomy assignment tools (BLASTn vs. Naïve Bayesian Classifier). In fact, the bioinformatics part of HTS studies have become an unavoidable field of science to integrate to microbial molecular ecology studies, and bioaerosol are not an exception.

Bioinformatics

The avalanche of big data generated by HTS platforms at an extraordinary rate has made bioinformatics indispensable to modern molecular ecology. Actually, there is a certain reluctance toward bioinformatics by some scientists due to the command line tools and programming skills needed for sequence processing and diversity analyses. Therefore, bioinformatics should be made accessible to a vast majority of potential daring users. Knowing which analyses to conduct and which tools to apply remains confusing for bioaerosol scientists, as a litany of tools and data resources are now available for characterizing microbial communities. Currently, microbial molecular data from bioaerosol studies are obtained predominantly using 16S rRNA gene sequencing surveys that provide a characterization of bacterial and archaeal diversity. In studies using 16S rRNA gene sequencing, the choice of primer set depends on a number of factors, including compatibility with previous studies and the specificities of the primers (Soergel *et al.*, 2012). 16S rRNA gene sequence data from different microbial environments present bioinformatical, statistical, and computational challenges. The most widely used bioinformatics tools are QIIME and mothur (Schloss *et al.*, 2009; Caporaso *et al.*, 2010). Both packages are open source and have online tutorials and forums that takes the users to a step-by-step analysis of the 16S rRNA gene sequences. Although the bioinformatics pipeline may seem to be the same for eukaryotic marker genes as for bacterial marker genes, there are no standardized bioinformatics protocols for ITS rRNA gene sequences as for 16S rRNA gene analyses. The lack of a standard marker gene and a reference database may be the reason behind that. The bioinformatics workflow used for the ITS sequences differs greatly from the one for the 16S rRNA gene in the alignment algorithm as the ITS region is of different lengths compared to the 16S rRNA gene. For this reason, amongst others, OTU clustering, reference databases, assigning taxonomy, diversity metrics, data visualization, and statistical modeling should be specific to ITS sequences analyses for the characterization of fungal communities. The UNITE database is often used for ITS sequence-based analyses of fungal sequences (Abarenkov *et al.*, 2010). On the other hand, the 18S rRNA gene can, generally, be used to analyze eukaryotic communities in the same manner as 16S rRNA genes are used. The SILVA database contains many eukaryotic regions and can be used for such analyses. However, one should confirm that the region of the 18S gene amplified discriminates between the taxa studied and should be aware that the 18S rRNA gene is not sufficient to characterize the fungal diversity and will likely end up to be of questionable utility.

When it comes to HTS, PCR errors are common, and are sometimes difficult to detect. Chimeras, which are caused by incomplete extension of DNA strand during amplification that make up a recombination between two sequences, can cause biases in diversity result, particularly the alpha metrics (Ley *et al.*, 2008; Haas *et al.*, 2011). Multiple chimera checking software are available and they often have different filtering methods. One should look at the one that fits adequately with the project (Ley *et al.*, 2008; Edgar *et al.*, 2011; Quince *et al.*, 2011; Wright *et al.*, 2012).

Data filtering is often made at the same stage as demultiplexing where each sequence is assigned to a sample based on the barcode information. Quality threshold includes quality scores, read length and the presence of ambiguous base calls. After quality filtering, one way to identify the microbial groups is through OTU analyses where sequences are clustered together based on sequence identity. As a matter of fact, there is different OTU clustering algorithms and the use of any one affects greatly the findings and interpretations of data. In *de novo* OTU clustering, sequences are clustered into OTUs by comparing them to the whole dataset, without the use of a reference (Westcott and Schloss, 2015). In contrast, closed OTU clustering uses a reference sequence database, whereby the sequences that don't match the reference sequence database are discarded. Open-reference OTU clustering is a two-step process combining both of the last algorithm described. First, closed-reference OTU clustering is done followed by *de novo* clustering of sequences that fail to match to the reference database. Each of the clustering methods have pros and cons and should be chosen with a particular attention. For example, if one must combine datasets that have sequences from different regions of the 16S rRNA gene or ITS rRNA gene, the closed reference algorithm should be used, as sequences from different regions of the same rRNA gene would cluster into different *de novo* OTUs. In contrast, using the closed reference algorithm in samples coming from an undiscovered environment may lead to a big percentage of the sequences being discarded due to a failure to match a reference database.

Labeling the OTUs is the next step using taxonomy assignment algorithm with a reference database. For the 16S rRNA gene, the three main databases are: Greengenes, Ribosomal Database Project (RDP), and SILVA (Cole *et al.*, 2009; McDonald *et al.*, 2012;

Quast *et al.*, 2013). For fungi, the UNITE database is the most used one. The microbial diversity analysis is typically described within samples (alpha diversity) and between samples (beta diversity). Multiple scripts for data visualization are available through QIIME, mothur and R. A particular attention should be given when choosing the classification and clustering methods depending on the metadata information available about the samples. For example, classification methods can be used to determine which taxa differ between predefined groups of samples. On the other hand, clustering methods does not make use of any prior knowledge about the samples. Both methods use in-between sample distance metrics and the specificities of each method used can affect the outcome and the interpretation of the analyses. For this reason, it is mandatory to use several different ways of classification and clustering to ensure that the existence of clusters is not dependent on just one set of parameters.

Diversity analyses include alpha and beta measures, statistical significance of sample groupings, differential abundance of taxa in different groups of samples, taxonomic analyses, and correlations between abundances (relative or absolute) and numerical metadata (e.g., days, temperature, relative humidity, etc.). Different taxonomic assignment method exist (not specific to amplicon-based HTS): similarity-based (BLAST, BOLD, METAPHYLER, MG-RAST); phylogeny-based (NJ, SAP, PPLACER, EPA); composition-based (KNN Classy method by mothur, OTU-picking by QIIME, RDP Classifier, UCLUST); hybrid methods (FUZZYD2, MEGAN); Bayesian treeless methods (Coalescent Assigner, Segregating Sites Assigner); Machine learning (BPSI, SVM classifier). At last, statistical modeling can be used to explain the variations observed between the different samples. As many covariates can be included and that many parameters can be statistically controlled, we strongly recommend the consultation of a statistician or a biostatistics expert during the experimental design and the analysis stages.

Recently, a new trendy method don't impose a dissimilarity threshold to analyze HTS gene markers nor a reference database. Amplicon Sequence Variants (ASVs) prone a better amplicon resolution by distinguishing sequence variants differing by one nucleotide (Eren *et al.*, 2015; Tikhonov *et al.*, 2015; Callahan *et al.*, 2016; Edgar, 2016; Amir *et al.*, 2017; Callahan *et al.*, 2017). ASVs most prominent advantage, compared to OTU-based methods, is the combination of the benefits from overcoming limitations inherent to closed-reference and *de novo* methods. For instance, closed-reference OTUs cannot document biological variations outside of the reference database used for their construction. On the other hand, the validity of *de novo* OTUs outside of the dataset in which they were defined is also questionable, which make cross-studies comparison invalid. While ASVs capture all biological variations present in a dataset, and ASVs inferred from a given dataset can be reproduced in future datasets and validly compared (Callahan *et al.*, 2017). However, ASVs method also comes with its share of limitations. Allowing 100% sequence similarity may lead to a wrong differentiation between the SNPs of the same species. In addition, the zero percent difference may give an extremely high number of ASVs in a sample, which, in return, causes the missing of the core microbiome information (unpublished data). Above all, the same genome can contain multiple ASVs if there is multiple copies of the targeted gene. For this matter, ASVs can be validly compared between studies, only when the same primers were used on the targeted gene. Furthermore, the high variability of the ITS region makes us reconsider the automatic replacement of the traditional OTUs by ASVs. To sum up, ASVs and *de novo* OTUs are more precise in describing diverse biological sequences in a less represented environment in reference databases like bioaerosols, compared to closed-reference OTUs. Most importantly, no matter the methodology used, downstream analyses should consider the methodological differences, accordingly.

The diverse biological sequences are identified by comparison to a database. As mentioned throughout this chapter, UNITE is the database used for the molecular identification of fungi. Without a doubt, it is a better choice when working with the fungal ITS region, as other databases, like NCBI or SILVA are not specifically curated for ITS identification. The UNITE database is regularly updated and annotated; thus, it continues to show tremendous improvements in the sequence management of fungal ITS (Nilsson *et al.*, 2019a,b). Although some databases contain an enormous number of sequences due to the fact that sequence deposition is easy an open to anybody, the risk of erroneous identification is also multiplied. In the contrary, UNITE is subject to quality control by ITSx and UCHIME in an attempt to reject non-ITS and chimeric sequences. When working with a less characterized environment like air (in comparison to soil and water), the quality control of sequences in a database is greatly appreciated. However, the representative sequences of ITS1 and ITS2 in UNITE is not known. According to the results obtained in Chapter 2, more unidentified fungi and plant identification were associated to ITS2 in datasets obtained from air samples in compost, biometanization, and dairy farms. Earlier this year, UNITE curators stated that they are working on adding more ITS2-derived HTS studies to UNITE (Nilsson *et al.*, 2019a,b). It would be valuable to address the current state of ITS2 sequences in the UNITE databases. In addition, annotated UNITE sequences covers not only taxonomic names, but also country of collection, and substrate of collection. Currently, UNITE uses the default NCBI Taxonomy classification complemented by Index Fungorum and MycoBank. Sequences with a confusing taxonomic annotation are flagged by experienced users for manual correction by UNITE curators. In the long term, UNITE is re-annotating, and re-identifying conflicting taxonomic information. The original names are kept for reference tracking accuracy.

In molecular microbial ecology studies, phylogeny allows the study of the evolutionary relation between species based on mathematical algorithms that compares DNA sequences. Particularly, phylogeny analyses are useful when comparing microbial community members between different samples, and by incorporating information on the relative relatedness between the microbes. Thus, the use of a reliable phylogenetic tree is necessary when analyzing diversity with a phylogenetic measure. A phylogenetic tree is a diagram with branches showing the evolutionary relationships between species. Because the 16S rRNA gene sequence contains both highly conserved regions for primer design (PCR-amplification) and hypervariable regions to identify phylogenetic characteristics of microbes, it became the most widely used marker gene for profiling bacterial communities (Lane *et al.*, 1985; Tringe and Hugenholtz, 2008; Yang *et al.*, 2016). As ITS sequences are subject to intraspecific variability the construction of a phylogenetic tree is not recommended (Nilsson *et al.*, 2008). Actually, different tree construction methods

(clustalw, and different programs within the PHYLIP package) led to conflicting phylogenetic results using the same dataset (unpublished data). This issue is known amongst the scientific community studying fungal diversity. Therefore, when analyzing fungal diversity with ITS datasets, measures including phylogenetic information are not recommended. Hopefully, many alternatives are available to compare microbial composition between samples without the use of phylogeny. Another popular alternative amongst phylogeny aficionados is the use of the 18S rRNA gene sequences as a phylogenetic marker for the fungal kingdom. Although the 18S rRNA have promising characteristics to build a phylogenetic framework for fungi (Yarza *et al.*, 2017), it shows a poor potential in describing the full extent of fungal diversity (Liu *et al.*, 2015).

Although the bioinformatics workflows described above were developed for different environments many of the same issues apply to microbial communities of different habitats. Thus, they can be applied to bioaerosol samples as well. In general, the different projects presented in this chapter encourage researchers entering the field to use bioinformatics tools to analyze the microbial molecular ecology results obtained in different bioaerosol environments. This active research area needs more standardized protocols that will help build a fungal bioaerosol public database that will allow cross-comparative studies around the world and give this field of study a great dash.

Conclusion

This chapter presented a comprehensive framework for the utility of HTS in the study of fungi in aerosols. The concern came mainly from the significant gap in fungal diversity of aerosols in occupational environments. Certainly, having a wider portrait of fungi that could represent a risk for exposed individuals in concerned environments represent an important piece of the puzzle for occupational exposure studies. Plus, combining the description of the fungal profiles of bioaerosols to other components like quantifying the fungal biomass, the association with traditional culture methods, the association of aerosols with the source, and the environmental variables explaining the fungal community composition served as a methodology approval and has brought new answers to fill the gap of fungi exposure in occupational environments. Looking ahead, key research directions which could follow up on the methodological contributions of this chapter could include the HTS of long reads using the PacBio or Nanopore technology covering the whole ITS region. The outcome could be compared to the approach targeting ITS1 or ITS2 to characterize fungal diversity in aerosols. In terms of occupational exposure, future works could include the measuring of health problems amongst the workers of the sampled environment. This way, fungal composition and concentration can be linked to specific health conditions, especially if the number of visits in the sampling campaign is very high. For this matter, it is important to shift attention to new ways of designing bioaerosol exposure studies in order to prevent the replication of previous flaws (e.g., different study designs, methods and analyses which makes it impossible to compare the results). Eventually, the goal is to set exposure guidelines referring to health-related exposure limits.

Introduction

Studies already reported that swimming pool facilities have contributed to the dissemination of fungal infections (Seebacher *et al.*, 2008). Most of the studies performed focused on dermatophytes and health effects (tinea pedis and onychomycosis) (Ali-Shtayeh *et al.*, 2003; Gudnadóttir *et al.*, 1999). However, besides dermatophytes, other clinically relevant fungi such as *Fusarium* spp., *Aspergillus* spp., and *Candida* spp., were showed on different environmental matrices from swimming pools facilities, such as surfaces, water and in indoor air (Buot *et al.*, 2010; Jankowski *et al.*, 2017; Viegas *et al.*, 2011).

Tinea pedis and onychomycosis are prevalent among swimming pool visitors (Kamihama *et al.*, 1997; Shemer *et al.*, 2016) and workers (Viegas *et al.*, 2011). Indeed, surfaces from the facilities may contain skin fragments from infected persons leading to the infection spread when infected skin fragments adhere to the feet of uninfected individuals while walking barefoot on the contaminated surfaces (English and Gibson, 1959).

To assess mycological contamination, it's important to consider the fungal spore's dispersion on air and surfaces. Type of sporulation and spore characteristics must be considered (size, density, colony structure and rugosity) as well as additional environmental characteristics, such as surface vibrations, smoothness and role as substrate (Roussel *et al.*, 2008). As such, culturing air samples as a stand-alone sampling approach to assess indoor fungal contamination is not enough. Indeed, surface analysis complements the fungal contamination characterization and can be used in order to identify contamination sources. It may also be apply to allow the evaluation of the efficacy of surface cleaning and disinfection procedures (Stetzenbach *et al.*, 2004).

Besides the sampling approach also the assays employed can influence the data obtained to perform the exposure assessment. Indeed, several constraints are being reported regarding the use of culture based-methods (Degois *et al.*, 2017; Viegas *et al.*, 2019a) and suggesting the use of molecular tools in parallel (Viegas *et al.*, 2019a).

This study aims to perform a scope review regarding the fungal contamination assessments performed on swimming pools and fitness centers aiming the identification of further research needed on these specific facilities.

Materials and methods

The available data from January 1st, 2000 to December 31st, 2019 was reviewed. The terms used were to identify studies were the fungal contamination in public swimming pools and fitness centers was assessed. PubMed, Scopus and Web of Science (WoS) were the databases chosen, and the search terms were "fungal contamination in swimming pools" and "fungal contamination in fitness centers". From this search, a total of 2907 papers were recovered from all databases. Articles that did not meet the inclusion criteria and duplicates were excluded from further analysis (Table 1). After eliminating the duplicates and articles that did not meet the criteria, a total of fifteen articles were further analyzed.

Results

The initial research resulted in a total of fifteen articles. From those articles, nine referred to indoor swimming pools alone (Brandi *et al.*, 2007; Ekowati *et al.*, 2018, 2017; Fadaei and Amiri, 2014; Itah and Ekpombok, 2004; Jankowski *et al.*, 2017; Karimi *et al.*, 2019; Rafiei and Amirrajab, 2010; Rasti *et al.*, 2012); one referred to both indoor and outdoor pools (Papadopoulou *et al.*, 2008), which studied indoor and outdoor public swimming pools, one hospital hydrotherapy pool and one private outdoor pool; one studied an hospital physical therapy pool (Buot *et al.*, 2010); three articles studied gymnasiums/sports centers with swimming pools (Małecka-Adamowicz *et al.*, 2019; Viegas *et al.*, 2011, 2010); and one article studied gymnasiums (Ramos *et al.*, 2016).

From all the studies considered, four of them used only water sampling (Fadaei and Amiri, 2014; Itah and Ekpombok, 2004; Papadopoulou *et al.*, 2008; Rasti *et al.*, 2012); three used only air sampling (Małecka-Adamowicz *et al.*, 2019; Ramos *et al.*, 2016; Viegas *et al.*, 2010); and two of them used only surface sampling (Buot *et al.*, 2010; Jankowski *et al.*, 2017). The remaining six studies combined either two or three of these matrixes: Rafiei and Amirrajab (2010), Ekowati *et al.* (2017) and Karimi *et al.* (2019)

Table 1 Criteria for inclusion and exclusion of the articles used

Inclusion criteria	Exclusion criteria
Articles in English language;	Articles in other languages (for articles)
Articles published from January 1st, 2000 to December 31st, 2019	Articles published prior to 2000
Articles published anywhere	
Articles related to fungi assessment in swimming pools and fitness centers	Articles related to biologic samples from gym/pool users (exclusive)
Articles related to swimming pools and fitness centers	Articles containing information from natural water sources
Scientific original articles on the topic	Abstract of congress, Reviews/State of the art, reports: used for discussion
Identification of fungi to the genera level (at least)	

combined water and surface sampling; Viegas *et al.* (2011) combined air and surface sampling; and Brandi *et al.* (2007) and Ekowati *et al.* (2018) used all three matrixes to assess fungal contamination (Brandi *et al.*, 2007; Ekowati *et al.*, 2018, 2017; Karimi *et al.*, 2019; Rafiei and Amirrajab, 2010; Viegas *et al.*, 2011).

From the nine articles that used water sampling (Brandi *et al.*, 2007; Ekowati *et al.*, 2018, 2017; Fadaei and Amiri, 2014; Itah and Ekpombok, 2004; Karimi *et al.*, 2019; Papadopoulou *et al.*, 2008; Rafiei and Amirrajab, 2010; Rasti *et al.*, 2012), all but one (Fadaei and Amiri, 2014), which used pour plate technique used the membrane filtering technique to analyze this matrix. All six articles that sampled air (Brandi *et al.*, 2007; Ekowati *et al.*, 2018; Małecka-Adamowicz *et al.*, 2019; Ramos *et al.*, 2016; Viegas *et al.*, 2011, 2010) did so using air impaction technique. Six studies performed surface sampling: the majority of them (five studies) did so with contact plates (Brandi *et al.*, 2007; Buot *et al.*, 2010; Ekowati *et al.*, 2018, 2017; Jankowski *et al.*, 2017), two of them performed sampling using sterile carpet (Karimi *et al.*, 2019; Rafiei and Amirrajab, 2010), and two of them used surface swabs (Karimi *et al.*, 2019; Viegas *et al.*, 2011).

All but three of the analyzed studies used morphological identification exclusively: two of them used both morphological and molecular identification (Brandi *et al.*, 2007; Ekowati *et al.*, 2017), and one used molecular identification alone (Ekowati *et al.*, 2018).

Sampling was, in some cases, performed twice in the same day, once in the morning, before activities, and in the evening (Itah and Ekpombok, 2004; Ramos *et al.*, 2016). Sampling was performed in different seasons (Brandi *et al.*, 2007; Buot *et al.*, 2010; Fadaei and Amiri, 2014; Jankowski *et al.*, 2017; Papadopoulou *et al.*, 2008; Rafiei and Amirrajab, 2010; Rasti *et al.*, 2012), whereas in some studies was only performed once (Ekowati *et al.*, 2018, 2017; Karimi *et al.*, 2019; Małecka-Adamowicz *et al.*, 2019; Viegas *et al.*, 2011, 2010).

Penicillium sp. was the most commonly found fungal species in air samples from some of the analyzed studies (Brandi *et al.*, 2007; Itah and Ekpombok, 2004). *Fusarium* sp. was the most reported in the surface samples (Brandi *et al.*, 2007; Buot *et al.*, 2010; Viegas *et al.*, 2011), while in the water samples the most common was *Alternaria* sp. (Buot *et al.*, 2010).

In the samples from Rafiei and Amirrajab (2010), Rasti *et al.* (2012), Fadaei and Amiri (2014), and Karimi *et al.* (2019), the most prevalent fungus was *Aspergillus* sp., and *Candida* sp. was the most prevalent in Jankowski *et al.* (2017). The most prevalent species in Ekowati *et al.* (2017, 2018) was *Phialophora oxyspora*.

Cladosporium sp. was the main source of contamination in several studies on air samples (Viegas *et al.*, 2010, 2011) and in the afternoon samples (Małecka-Adamowicz *et al.*, 2019; Ramos *et al.*, 2016), whereas in the morning samples of Ramos *et al.* (2016) the most significant contamination was from *Chrysosporium* sp. (Table 2).

Discussion

Due to this scope review it was possible to conclude that there is a wide spectrum of environments that include a swimming pool in their facilities. Indeed, it was possible to observe that although the majority was to develop only the activity of swimming in the facilities (Brandi *et al.*, 2007; Ekowati *et al.*, 2018, 2017; Fadaei and Amiri, 2014; Itah and Ekpombok, 2004; Jankowski *et al.*, 2017; Karimi *et al.*, 2019; Papadopoulou *et al.*, 2008; Rafiei and Amirrajab, 2010; Rasti *et al.*, 2012), others include different services available (Buot *et al.*, 2010; Małecka-Adamowicz *et al.*, 2019; Ramos *et al.*, 2016; Viegas *et al.*, 2011, 2010). As such, different variables favoring the fungal dissemination should be considered due to the different activities performed indoors (Roussel *et al.*, 2008).

As in other indoor environments studied (Santilli and Rockwell, 2003; Viegas *et al.*, 2019a, 2014; Wilson *et al.*, 2004) we should consider for assessing this specific indoor environment different sampling approaches. Active sampling such air impaction applied by several studies analyzed (Brandi *et al.*, 2007; Ekowati *et al.*, 2018; Małecka-Adamowicz *et al.*, 2019; Ramos *et al.*, 2016; Viegas *et al.*, 2011, 2010) combined with passive methods, namely surface swabs, contact plates or carpet samples (Brandi *et al.*, 2007; Ekowati *et al.*, 2018, 2017; Karimi *et al.*, 2019; Rafiei and Amirrajab, 2010; Viegas *et al.*, 2010) can give a more accurate characterization of fungal contamination. Different passive sampling methods are being used in other indoor environments and can be an added value also in this indoor environment. Indeed, settled dust and electrostatic dust collectors have already being reported as retrieving a more diversified fungal contamination data comparing with other passive methods (Viegas *et al.*, 2019b, 2018).

Table 2 Articles used in this review

Database	Country	Type of environment analyzed	Type of sample obtained	Sampling method	Fungal identification	Results	Reference
PubMed	Nigeria	Ten swimming pools	Water samples	Water samples	Morphological identification	The most common fungal groups identified were <i>Penicillium</i> sp., <i>Rhizopus</i> sp., <i>Aspergillus versicolor</i> , <i>Fusarium</i> sp., <i>Trichophyton mentagrophytes</i> , <i>Mucor</i> sp., <i>Candida albicans</i> , <i>Aspergillus niger</i> , and <i>Absidia</i> sp	(Itah and Ekpombok, 2004)
	Italy	10 Italian swimming pools	Water and surface samples (swimming pool edge, shower pans and locker room floors)	Settle plates, air impaction, water samples	Morphological and molecular identification	<i>Penicillium</i> spp., <i>Aspergillus</i> spp., <i>Cladosporium</i> spp. and <i>Alternaria</i> sp., were present in all air and surface samples from the swimming area. <i>Fusarium</i> spp. was the most common fungi isolated from surface samples	(Brandi et al., 2007)
	Greece	Three indoor swimming pools (a teaching pool, a competition public pool, a hydrotherapy pool) and two outdoor swimming pools (a hotel semi-public and a residential private pool)	Water samples	Water samples	Morphological identification	The swimming pool with the highest prevalence of isolates and multi-resistant isolates was the hydrotherapy pool. <i>Candida albicans</i> , <i>Aspergillus</i> spp., <i>Mucor</i> spp., <i>Alternaria</i> spp., <i>Rhizopus</i> spp., <i>Trichophyton</i> spp., and <i>Penicillium</i> spp. were all isolated	(Papadopoulou et al., 2008)
	Switzerland	Hospital physical therapy swimming pool	Surface samples from three showers, three synthetic carpets and two tiled locations	Contact plates	Morphological identification	All samples were positive for fungi. <i>Candida famata</i> was the most common yeast in shower areas. <i>Fusarium</i> spp. was present in all studied areas	(Buot et al., 2010)
	Iran	Ten indoor public swimming pools	Water samples from the swimming pools and foot-washing sink. Environmental samples from shower bath area, margin of pool walls, dressing rooms, and slippers	Sampling using a piece of sterile carpet	Morphological identification	The most common dermatophytes were <i>Trichophyton mentagrophytes</i> , <i>T. rubrum</i> , <i>T. verrucosum</i> and <i>Epidermophyton floccosum</i> . <i>Aspergillus</i> sp., <i>Penicillium</i> sp. and <i>Mucor</i> sp. were the most common saprophytic fungi	(Rafiei and Amirrajab, 2010)
	Iran	Two indoor swimming pools	Water samples and surface samples (showers, dressing rooms and bottom of the swimming pools)	Not described	Morphological identification	The most prevalent fungi were <i>Aspergillus</i> sp., <i>Penicillium</i> sp., <i>Nocardia</i> sp., <i>Cladosporium</i> sp., <i>Rhizopus</i> sp., <i>Scopulariopsis</i> sp., <i>Fusarium</i> sp., and <i>Mucor</i> sp. The most contaminated sites were the showers	(Fadaei and Amiri, 2014)
	Netherlands	Six pools in a swimming pool facility	Water and surface samples	Contact plates and surface swabs, water samples	Morphological and molecular identification	Highest fungal concentrations in water and on surfaces were found in the recreational pool and on a flexibeam, respectively. <i>Phialophora oxyspora</i> and <i>Phoma</i> spp. were the most frequently identified groups	(Ekowati et al., 2017)

	Poland	Eight indoor swimming pools	Surface samples from shower sinks and women's dressing room floors	Contact plates	Morphological identification	<i>Candida</i> spp., <i>Rhodotorula rubra</i> , <i>Aspergillus</i> spp. and <i>Trichophyton mentagrophytes</i> were the most common fungi	(Jankowski <i>et al.</i> , 2017)
	Netherlands	Seven swimming pool facilities	Water and floor surface samples, one air sample, and surface samples from one of the flexibeams. When possible, samples were taken from the cleaning tools used to clean the floors	Water samples, contact plates and air impaction	Molecular identification	Maximum fungal concentrations were found on surfaces. <i>Phialophora oxyspora</i> and <i>Trichosporon dohaense</i> were the most frequently isolated species, but only found in surface samples. <i>Penicillium</i> spp. and <i>Aspergillus</i> spp. were the dominant fungi in water and air	(Ekowati <i>et al.</i> , 2018)
	Iran	Two indoor swimming pools	Water samples, surface samples and carpet samples	Water samples, membrane filtration technique and carpet samples	Morphological identification	The pools were contaminated with dermatophytes (<i>Trichophyton mentagrophytes</i> and <i>Epidermophyton flucosomes</i>), yeasts, and opportunistic saprophytic fungi	(Karimi <i>et al.</i> , 2019)
WoS	Portugal	Ten gyms with swimming pools	Air samples	Air impaction	Morphological identification	Twenty-five different species of fungi were identified, with <i>Cladosporium</i> sp., <i>Penicillium</i> sp., <i>Aspergillus</i> sp., <i>Mucor</i> sp., <i>Phoma</i> sp. and <i>Chrysonilia</i> sp. as the most common	(Viegas <i>et al.</i> , 2010)
	Iran	Four indoor public swimming pools	Water samples	Water samples	Morphological identification	Twelve species of fungi were isolated, with <i>Aspergillus</i> sp., <i>Penicillium</i> sp., <i>Rhizopus</i> sp. and <i>Fusarium</i> sp. as the most common. The highest fungal contamination was observed in summer	(Rasti <i>et al.</i> , 2012)
	Portugal	Three gymnasiums in the city of Lisbon	Air samples	Air impaction	Morphological identification	In the morning period, the most common fungal species were <i>Chrysosporium</i> sp., <i>Chrysonilia</i> sp., <i>Neoscytalidium hialinum</i> , <i>Sepedonium</i> sp. and <i>Penicillium</i> sp.; <i>Cladosporium</i> sp., <i>Penicillium</i> sp., <i>Chrysosporium</i> sp., <i>Acremonium</i> sp. and <i>Chrysonilia</i> sp. were more prevalent at night	(Ramos <i>et al.</i> , 2016)

(Continued)

Table 2 Continued

Database	Country	Type of environment analyzed	Type of sample obtained	Sampling method	Fungal identification	Results	Reference
	Poland	Several sports facilities in Poland	Air samples	Air impaction	Morphological identification	At the sports field, <i>Cladosporium</i> sp. is the most common fungal group, as well as in the swimming pool and martial arts room. At the remaining sites their contribution was considerably lower. Several humidity indicator species, such as <i>Aspergillus fumigatus</i> , <i>A. versicolor</i> , <i>Trichoderma</i> sp., <i>Penicillium</i> sp., <i>Phialophora</i> sp., <i>Fusarium</i> sp. and <i>Ulocladium</i> sp. were recorded at indoor swimming pools. The air at the gym and sports hall contained molds of <i>Fusarium</i> sp. and <i>Acremonium</i> sp., as well as <i>Cladosporium</i> sp. The fitness room was contaminated with <i>Penicillium</i> sp.	(Matecka-Adamowicz <i>et al.</i> , 2019)
Scopus	Portugal	Ten indoor gyms with swimming pools	Air and surface sampling (in the floor surrounding the swimming pool; the floor surrounding the Jacuzzi; the stair's access to the swimming pool area; the floor of the training studios where most of the barefoot activities are performed and the changing/ locker rooms from each gender)	Air impaction and surface swabs	Morphological identification	In air samples: 25 species of molds were identified, with <i>Cladosporium</i> sp., <i>Penicillium</i> sp., <i>Aspergillus</i> sp., <i>Mucor</i> sp., <i>Phoma</i> sp. and <i>Chrysonilia</i> sp. as the most common. In surface samples: 37 different species of molds were isolated and the most frequent genera before and after cleaning and disinfection were <i>Fusarium</i> sp., <i>Penicillium</i> sp. and <i>Scytalidium</i> sp.	(Viegas <i>et al.</i> , 2011)

As regards the assays to be performed culture-based methods are crucial for assessing the exposure to microbial contamination, since the viable component of the fungal contamination, shows an higher impact regarding health effects (Cooley, 2000; Croston *et al.*, 2016; Huttunen *et al.*, 2003; Viegas *et al.*, 2019c). However, they should be combined with real-time PCR assay for targeting the indicators of harmful fungal contamination specific for each indoor environment, to better assess fungal contamination (Degois *et al.*, 2017; Viegas *et al.*, 2017). Of note, culture-based methods can reveal less abundant fungi in some indoor environments, when compared with more refined molecular tools. However, though in less counts some *Aspergillus* sections (opportunistic pathogens) found as the most prevalent in some studies (Fadaei and Amiri, 2014; Karimi *et al.*, 2019; Rafiei and Amirrajab, 2010; Rasti *et al.*, 2012) may represent a health risk for visitors and also workers who are exposed on a daily basis (Mbareche *et al.*, 2019).

Conclusions

Future endeavors should be performed to achieve an exposure assessment protocol specific for the indoor environments that comprise swimming pools, since they can work as additional fungal sources. The decisions regarding the sampling methods and the laboratory tools to apply to accomplish an accurate fungal contamination exposure assessment should be supported by scientific guidance to allow the risk characterization of users and workers.

Introduction

In buildings where intense animal breeding occurs, the air is usually contaminated with a high prevalence of microorganisms (Dutkiewicz *et al.*, 1994; Seedorf *et al.*, 1998; Radon *et al.*, 2002; Jo and Kang, 2005; Lee *et al.*, 2006; Sowiak *et al.*, 2011; Sowiak *et al.*, 2012). However, the sector of animal production where the highest prevalence of microorganisms was reported was poultry breeding (Seedorf *et al.*, 1998; Radon *et al.*, 2002; Sowiak *et al.*, 2012).

It is well known that fungi in indoor farm environments emerge and sporulate easily in low quality bedding or polluted feedstuffs. Pollutants accumulated in confined animal buildings can present a serious health hazard for workers (Karwowska, 2005; Chmielowiec-Korzeniowska *et al.*, 2018). Insufficient ventilation and the presence of particulate matter raise the risk of exposure to bioaerosols (Viegas *et al.*, 2019b). Bioaerosols consist of airborne bacteria, fungi, viruses and their by-products, endotoxins and mycotoxins (Oppliger *et al.*, 2008; Just *et al.*, 2009; Viegas *et al.*, 2012a) and also non-viable particles, formed by items such as feces, litter, feed and feathers (Viegas *et al.*, 2012a).

Airway inflammation caused by a non-allergic mechanism has been well established as the main respiratory health problem for those working in animal production buildings with heavy dust exposure, especially in swine and poultry farms (Olenchok *et al.*, 1982; Mutel and Donham, 1983; Rylander, 1986; Melbostad *et al.*, 1997; Iversen *et al.*, 2000; Kirkhorn and Garry, 2000; Viegas *et al.*, 2012b). Among fungi the genera *Aspergillus*, *Penicillium*, *Cladosporium*, *Alternaria*, *Rhizopus*, *Scopulariopsis* and *Trichophyton* are commonly found inside breeding buildings (Gemeinhardt and Wallenstein, 1985; Lugauskas *et al.*, 2004; Jo and Kang, 2005; Sowiak *et al.*, 2012). Thus, the inhalation of fungal spores has been linked to hypersensitive lungs (Mutel and Donham, 1983; Viegas *et al.*, 2012b). *Aspergillus* species have been closely related among the filamentous fungi to asthma exacerbations and other allergic respiratory diseases (Viegas *et al.*, 2019a). Particles with an average aerodynamic diameter of 1–4 µm, like *A. fumigatus* conidia, are found in the lower respiratory tract since they are small enough to pass through the terminal airways and enter the pulmonary alveoli (Viegas *et al.*, 2019a).

Occupational exposure can occur by inhalation of the dust produced during the processing and handling of contaminated crops and feed. This contamination path creates harmful health effects for workers (Chang *et al.*, 2001; Cormier *et al.*, 2000; Reboux *et al.*, 2006; Viegas *et al.*, 2019a,b) and for animals, especially for avian species (Lair-Fullerger *et al.*, 2006).

Respiratory problems are well-recognized by these workers, resulting in elevated morbidity and mortality from certain respiratory disorders. Several studies have shown that the prevalence of work-related respiratory problems such as wheeze, cough and dyspnea is extremely high (23–50 per cent) (Rylander *et al.*, 1990; Skórska *et al.*, 1998; Radon *et al.*, 1999; Viegas *et al.*, 2019a,b). The main respiratory symptoms due to fungi exposure include allergic bronchopulmonary mycoses (ABPM), pneumonitis with hypersensitivity, fungal sinusitis, allergic rhinitis, and extreme fungal sensitized asthma (SAFS) (Simon-Nobbe *et al.*, 2008; Viegas *et al.*, 2019a,b). Additionally, under Hazardous Biological Agents Regulation, enforced by Directive 2000/54/EC of the European Council, farmers are classified into the groups of occupationally exposed to biological agents at their workplace. It is also important to highlight that most of the work on airborne fungi in various agricultural environments used only culture-based sampling methods (Predicala *et al.*, 2002; Lubiński *et al.*, 2005; Chmielowiec-Korzeniowska *et al.*, 2018). Therefore, these studies neglected non-cultural airborne fungi, which can be as allergic or harmful as culturable fungi (Dutkiewicz *et al.*, 2011; Chmielowiec-Korzeniowska *et al.*, 2018) and, enhance health risks to animal production workers.

As such, this study aims to gather and highlight information regarding animal production environments, its dominant species, the most commonly used sampling and analytical methods and of which show more reliable and accurate results when assessing or monitoring fungal burden in these kinds of occupational environments.

Materials and methods

For this study was performed a well-structured search of published data and information in the public domain between 1st of January 2000 and 31st of June 2020. Baseline parameters were selected following the PRISMA methodology to identify and select studies referring to animal production occupational environments that assessed fungi, selecting only English and original

Table 1 Inclusion and exclusion criteria in the articles selected

Inclusion criteria	Exclusion criteria
Articles published in the English language;	Articles published in other languages
Articles published from 1st January 2000 to 31st June 2020	Articles published prior to 2000
Articles published in any country	
Articles related to fungi assessment in animal production settings	Articles related exclusively to biological samples or without mention of fungi quantification.
Original scientific articles on the topic	Abstracts of congress, reports, reviews or state of the art articles

**Fig. 1** PRISMA methodology of selection of papers.

papers. Appropriate search terms were employed in the selected databases (PubMed, Scopus and Web of Science), mainly focusing in occupational settings and fungi assessment. However, since the number of papers selected in the databases were lower than the expected, search terms were also employed in other sources, so that more robust results were achieved. The final result of this search resulted in 15 original papers and all the articles that do not meet the selected inclusion criteria were excluded ([Table 1](#)). The main findings of the studies were highlighted and compared for consistency, resulting in a final selection of papers ([Fig. 1](#)).

Results

As a result of the structured literature review, a total of 15 articles were selected since the inclusion criteria were verified ([Table 2](#)). Different occupational environments regarding animal production (poultry houses, swine farms and other facilities) were considered. The sampling and analytical methods used, as well as the main findings found in each study were analyzed.

The main setting found among the selected studies were poultry ([Kim et al., 2008](#); [Sabino et al., 2012](#); [Sowiak et al., 2012](#); [Viegas et al., 2012a,b](#); [Lawniczek-Walczyk et al., 2013](#); [O'Brien et al., 2016](#)) and swine farms ([Adhikari et al., 2004](#); [Kim et al., 2008](#); [Sabino et al., 2012](#); [Viegas et al., 2013](#); [Costa et al., 2014](#); [Chmielowiec-Korzeniowska et al., 2018](#); [Viegas et al., 2018b](#)) making a

Table 2 Papers included in the review

Database	Title	Country	Environment description	Sampling methods	Analytical methods	Results	Main findings	References
PubMed	Occupational exposure to airborne microorganisms, endotoxins and β -glucans in poultry houses at different stages of the production cycle	Poland	3 Poultry houses	Personal air filtration and impaction air sampling	Culture-based methods	<i>Aspergillus</i> spp. <i>Penicillium</i> spp. <i>Scopulariopsis</i> spp.	Professional activities in poultry farms are associated with constant exposure to large quantities of airborne microorganisms. Filter method showed incomplete information regarding qualitative results, however it stands as a good reference for total microbial counts.	(Lawniczek-Walczyk <i>et al.</i> , 2013)
	Occupational exposure level of pig facility workers to chemical and biological pollutants	Poland	1 Swine farm	Stationary air filtration	Culture-based methods	<i>Aspergillus</i> spp. <i>Cladosporium</i> spp. <i>Fusarium</i> spp. <i>Penicillium</i> spp. <i>Rhizopus</i> spp. <i>Ulocladium</i> spp. <i>Trichoderma</i> spp.	VOC concentration exceeded Polish recommended values regardless of the season, however ventilation plays a major role on the microbiological contamination.	(Chmielowiec-Korzeniowska <i>et al.</i> , 2018)
Scopus	Effects of disinfectant fogging procedure on dust, ammonia concentration, aerobic bacteria and fungal spores in a farrowing-weaning room	Italy	1 Swine farm	Impaction air sampler	Culture-based methods	Fungal spore range: 0 CFU m^{-3} – $1.84 \times 10^2 \text{ CFU m}^{-3}$	The reduction of fungal spores and the smaller fractions of particles were associated with the oxidizing effect of the disinfection procedure.	(Costa <i>et al.</i> , 2014)
	Pulmonary illness as a consequence of occupational exposure to shrimp shell powder	Canada and Norway	3 Shrimp processing units	Stationary air filtration	Culture-based methods, MALDI-TOF	<i>Aspergillus fumigatus</i> , <i>Penicillium chrysogenum</i> , <i>Penicillium rugulosum</i>	This study showed that exposure to shrimp powder aerosols have a negative impact on the workers health, due to the high fraction of inhalable dust and microorganisms present.	(Bertelsen <i>et al.</i> , 2016)
	High throughput genomic sequencing of bioaerosols in broiler chicken production facilities	USA	Poultry farms	Personal air filtration	Illumina genome sequencing and analysis	Ascomycota phylum prevalence: 1.4%	The reduction of fungal spores and the smaller fractions of particles were associated with the oxidizing effect of the disinfection procedure.	(O'Brien <i>et al.</i> , 2016)
Web of Science	Airborne contaminants in conventional laboratory rabbit rooms	Finland	2 Rabbit rooms	Personal and stationary air filtration	Culture-based methods	<i>Aspergillus versicolor</i> , <i>Aspergillus</i> sp. <i>Cladosporium</i> sp. <i>Penicillium</i> sp.	Good ventilation and hygiene may reduce airborne contaminants concentration, however pathogenic species were found that may pose a health hazard to the workers.	(Kaliste <i>et al.</i> , 2002)

(Continued)

Table 2 Continued

Database	Title	Country	Environment description	Sampling methods	Analytical methods	Results	Main findings	References
	Evaluation of environmental circumstance within swine and chicken Houses in South Korea for the production of safe and hygienic animal food products	South Korea	6 Swine houses and 7 Chicken houses	Impaction air sampling	Culture-based methods	Swine houses fungal range: 1.2×10^1 CFU m^{-3} – 2.5×10^4 CFU m^{-3} Chicken houses fungal range: 6.8×10^2 CFU m^{-3} – 1.0×10^5 CFU m^{-3}	The values found in this study suggests that these facilities may not represent a health hazard to the workers, however its reported that the environments of swine and poultry facilities contribute to the development of respiratory tract diseases and other symptoms.	(Kim <i>et al.</i> , 2008)
	Air contaminants in animal production: the poultry case	France	7 Poultry farms	Impaction air sampling	Culture-based methods	<i>Aspergillus</i> sp. <i>Penicillium</i> sp. <i>Rhizopus</i> sp. <i>Scopulariopsis brevicaulis</i>	Exposure level assessment to bioaerosols in these occupational settings are needed due to the already reported cases of hypersensitivity pneumonitis and other respiratory symptoms. Environmental factors may influence fungal load.	(Viegas <i>et al.</i> , 2012a)
	Production of recycled manure solids for use as bedding in Canadian dairy farms: II. Composting methods	Canada	12 Experimental dairy rooms	Impinger air sampling	Culture-based methods	Culturable fungi range: 3.0×10^2 CFU m^{-3} – 5.6×10^4 CFU m^{-3}	Composting materials may have effects on the concentration of spore-forming organisms in milk. In humid climate the temperature should be kept at thermophilic temperatures to avoid the increase of the microbial load.	(Fournel <i>et al.</i> , 2019)
Other Sources	Assessment of human exposure to airborne fungi in agricultural confinements: Personal inhalable sampling versus stationary sampling	USA	1 Swine farm and 1 Dairy farm	Personal and stationary air filtration	Culture-based methods	Stationary air sampling: <i>Aspergillus</i> / <i>Penicillium</i> sp. <i>Cladosporium</i> sp. Personal air sampling: <i>Aspergillus</i> / <i>Penicillium</i> sp. <i>Cladosporium</i> sp.	No major difference was detected between the two sampling methods. Button samplers seem to be a reliable method do assess the workers exposure to inhalable fungi in agricultural environments.	(Adhikari <i>et al.</i> , 2004)
	Occupational Exposure to <i>Aspergillus</i> by Swine and	Portugal	7 Poultry farms and 7 Swine farms	Impaction air sampling,	Culture-based methods	<i>Aspergillus</i> genus prevalence: 22% <i>Aspergillus</i>	High fungal load was verified in these kinds of facilities, mainly of <i>Aspergillus</i> and <i>Penicillium</i>	(Sabino <i>et al.</i> , 2012)

Poultry Farm Workers in Portugal			surface sampling by swabbing		<i>versicolor</i> , <i>Aspergillus flavus</i> , <i>Aspergillus fumigatus</i>	species. Total fungal load surpassed the recommended values for poultry houses in all the air samples.	
Fungal aerosol in the process of poultry breeding-quantitative and qualitative analysis	Poland	5 Poultry farms	Stationary air filtration	Culture-based methods	<i>Acremonium</i> sp. <i>Acremonium strictum</i> , <i>Aspergillus</i> sp. <i>Aspergillus fumigatus</i> , <i>Candida</i> sp. <i>Candida tropicalis</i> , <i>Geotrichum</i> sp. <i>Penicillium</i> sp. <i>Penicillium aurantiogriseum</i> , <i>Scopulariopsis</i> sp.	Fungi concentrations found often exceeded reference limit values. 88% of the fungal microflora were composed by molds and also pathogenic species were found.	(Sowiak <i>et al.</i> , 2012)
Comparison of indoor and outdoor fungi and particles in poultry units	Portugal	7 Poultry farms	Impaction air sampling	Culture-based methods	<i>Aspergillus flavus</i> , <i>Aspergillus</i> sp. <i>Penicillium</i> sp. <i>Rhizopus</i> sp. <i>Scopulariopsis brevicaulis</i>	Poultry farms are a reservoir of fungi and particles that may be re-aerosolized into the air resulting in emission of potential pathogenic fungi into the air, thus increasing the health hazards present in the work environment.	(Viegas <i>et al.</i> , 2012b)
Fungal Contamination in Swine: A Potential Occupational Health Threat	Portugal	7 Swine farms	Impaction air sampling, surface sampling by swabbing, bulk sampling of floor coverage	Culture-based methods	<i>Aspergillus versicolor</i> , <i>Cladosporium</i> sp. <i>Chrysosporium</i> sp. <i>Geotrichum</i> sp. <i>Mucor</i> sp. <i>Scopulariopsis brevicaulis</i> <i>Trichoderma</i> sp.	<i>Stachybotris</i> sp. should not be neglected when assessing swine barns due to its slow growth and to its toxin production potential. Pig houses have many possible sources of contamination that may also affect outdoor air quality and pose a threat to human health.	(Viegas <i>et al.</i> , 2013)
A Novel Multi-Approach Protocol for the Characterization of Occupational Exposure to Organic Dust—Swine Production Case Study	Portugal	5 Swine farms	Impaction and Impinger air sampling, surface sampling by swabbing	Culture-based methods, RT-PCR	Air samples: <i>Aspergillus</i> section <i>Circumdati</i> , <i>Aspergillus</i> section <i>Versicolores</i> , <i>Cladosporium</i> sp. Feed samples: <i>Cladosporium</i> sp. Surface samples: <i>Cladosporium</i> sp. <i>Scopulariopsis brevicaulis</i> Floor samples: <i>Penicillium</i> sp. <i>Alternaria</i> sp.	The use of different culture media, passive methods and molecular tools helps to achieve a more accurate mycobiota exposure assessment. Swine farm workers were exposed to a combination of several risk factors.	(Viegas <i>et al.</i> , 2018b)

total of 12 out of 15 articles. Two dairy farms (Adhikari *et al.*, 2004; Fournel *et al.*, 2019), a rabbit room (Kaliste *et al.*, 2002) and a shrimp processing plant (Bertelsen *et al.*, 2016) were also analyzed.

The air impaction method was used in 8 of the 15 studies (Kim *et al.*, 2008; Sabino *et al.*, 2012; Viegas *et al.*, 2012a,b, 2013; Lawniczek-Walczuk *et al.*, 2013; Costa *et al.*, 2014; Viegas *et al.*, 2018b), making it the most common method overall followed by the air filtration method used in 7 of the 15 studies (Kaliste *et al.*, 2002; Adhikari *et al.*, 2004; Sowiak *et al.*, 2012; Lawniczek-Walczuk *et al.*, 2013; Bertelsen *et al.*, 2016; O'Brien *et al.*, 2016; Chmielowiec-Korzeniowska *et al.*, 2018). Other methods were also employed, such as surface swabs (Sabino *et al.*, 2012; Viegas *et al.*, 2013, 2018b), impinger method (Fournel *et al.*, 2019) and bulk sample collection (Viegas *et al.*, 2013). The exclusive use of active methods were the most used approach reported in 12 out of the 15 studies (Kaliste *et al.*, 2002; Adhikari *et al.*, 2004; Kim *et al.*, 2008; Sowiak *et al.*, 2012; Viegas *et al.*, 2012a,b; Lawniczek-Walczuk *et al.*, 2013; Costa *et al.*, 2014; Bertelsen *et al.*, 2016; O'Brien *et al.*, 2016; Chmielowiec-Korzeniowska *et al.*, 2018; Fournel *et al.*, 2019) and the simultaneous use of active and passive methods (Sabino *et al.*, 2012; Viegas *et al.*, 2013, 2018b) was observed in 3 of the 15 studies. However, it was not observed in any study the use of passive sampling methods as a stand-alone method.

Regarding analytical methods culture-based methods was the most common approach across all studies, being performed in 14 out of the 15 studies (Kaliste *et al.*, 2002; Adhikari *et al.*, 2004; Kim *et al.*, 2008; Sabino *et al.*, 2012; Sowiak *et al.*, 2012; Viegas *et al.*, 2012a,b; Viegas *et al.*, 2013; Lawniczek-Walczuk *et al.*, 2013; Costa *et al.*, 2014; Bertelsen *et al.*, 2016; Chmielowiec-Korzeniowska *et al.*, 2018; Viegas *et al.*, 2018b; Fournel *et al.*, 2019) while the use of molecular tools for analytical assessment were observed only in 3 out of the 15 studies (Bertelsen *et al.*, 2016; O'Brien *et al.*, 2016; Viegas *et al.*, 2018b). *Aspergillus* section *Nidulantes* (formerly *Aspergillus* section *Versicolores*) (Kaliste *et al.*, 2002; Sabino *et al.*, 2012; Viegas *et al.*, 2013, 2018b) and *Scopulariopsis brevicaulis* (Viegas *et al.*, 2012a,b, 2013, 2018b) were both found in 4 out of 15 studies making both species the most identified across all studies.

Aspergillus was the genera most common among all the selected studies, found in 10 out of 15 studies (Kaliste *et al.*, 2002; Adhikari *et al.*, 2004; Sabino *et al.*, 2012; Sowiak *et al.*, 2012; Viegas *et al.*, 2012a,b; Lawniczek-Walczuk *et al.*, 2013; Viegas *et al.*, 2013; Bertelsen *et al.*, 2016; Chmielowiec-Korzeniowska *et al.*, 2018; Viegas *et al.*, 2018b), in which were reported species belonging to *Aspergillus* section *Fumigati* (*Aspergillus fumigatus*) (Sabino *et al.*, 2012; Sowiak *et al.*, 2012; Bertelsen *et al.*, 2016) and *Aspergillus* section *Flavi* (*Aspergillus flavus*) (Sabino *et al.*, 2012; Viegas *et al.*, 2012b). *Penicillium* was reported in 9 out of 15 studies (Adhikari *et al.*, 2004; Sowiak *et al.*, 2012; Viegas *et al.*, 2012a,b; Lawniczek-Walczuk *et al.*, 2013; Bertelsen *et al.*, 2016; Chmielowiec-Korzeniowska *et al.*, 2018; Viegas *et al.*, 2018b), *Scopulariopsis* sp. in 6 out of 15 studies and *Cladosporium* sp. in 5 out of 15 studies.

Discussion

The use of passive methods for sampling occupational environments allows a better quantification of the number of fungal species present and a sampling that is representative of longer periods of time (Viegas *et al.*, 2015a,b, 2017). The collection and analysis of feed and floor coverage samples during exposure assessment in animal production environments is an important tool as these matrices function as passive methods that are critical for bioburden assessment (Hayleeyesus and Manaye, 2014; Viegas *et al.*, 2020b). This approach was employed in 3 out of the 15 studies regarding swine and poultry farms (Sabino *et al.*, 2012; Viegas *et al.*, 2013, 2018b), considering these type of environmental matrices ensures that the microbiological characterization of the environment is carried out in a more comprehensive and complete way (Klánová and Hollerová, 2003; Stetzenbach *et al.*, 2004; Viegas *et al.*, 2016a,b, 2019b).

Regarding the analytical methods, in most papers (12 out of 15) culture-based methods were the only one used to perform fungal identification. However, this method has some disadvantages that should be considered such as the growth speed of some fungal species that can influence others when we're considering mixed cultures. As an example, the overgrowth of a specific species in a mixed culture, may cause a chemical competition and consequently lead to the inhibition of the growth of other species (Viegas *et al.*, 2015a,b; Dias and Viegas, 2020). That evidence supports the need to combine culture-based methods with molecular tools as we can see in 3 out of the 15 papers analyzed (Bertelsen *et al.*, 2016; Viegas *et al.*, 2018b). Nonetheless, it is important to highlight that all three papers used different molecular tools, and that these methods detain some specific characteristics that makes them more efficient such as its speed, extreme analytical sensitivity of detection, accuracy and the possibility to detect and identify dead or dormant microorganisms, as well as toxigenic strains from specific fungal species (Amann *et al.*, 1995; MacNeil *et al.*, 1995; Viegas *et al.*, 2015a,b; Dias and Viegas, 2020). Considering all the above, the use of molecular tools as an ally to culture-based methods should always be considered. Regarding the species prevalence, most studies (11 out of 15) presented *Aspergillus* spp. as one of the species with the highest prevalence. It has been reported that some sections of *Aspergillus* genera are opportunistic and increase the appearance of infections in immunocompromised individuals, and also of antifungal resistance, both in the clinical and in the environment (Fairlamb *et al.*, 2016; Nature Microbiology, 2017; Viegas *et al.*, 2020a,c; Dias and Viegas, 2020). There is also some other factors in *Aspergillus* spp. that gives them a higher occupational risk such as the pathogenic and toxigenic potential of some *Aspergillus* sections (*Flavi*, *Nidulantes*, *Circumdati*, *Nigri*, *Terrei*, *Fumigati*,...) (Varga *et al.*, 2015, 2018a, 2020a,c) that may cause several health complications such as chronic pulmonary aspergillosis, allergic bronchopulmonary aspergillosis and invasive aspergillosis (Lamoth, 2016). Therefore, the assessment of this genus should always be recommended. In animal production, the One Health approach should be considered, since these occupational environments require a dynamic relationship between the environment, animals and humans. When dedicated to animal production, it considers the impact caused by the products that come directly from the animals (e.g., Milk, Eggs, etc) in public health while guarantees food safety by establishing controlling measures (Predicala *et al.*, 2002; Chmielowiec-Korzeniowska *et al.*, 2018). Therefore, it is important to insure that high-quality water, feed, and equipment are used and precautions are placed in place to avoid the occurrence of

environmental contamination and disease transmission within the herd and animal handlers, safeguarding all animal products (Predicala *et al.*, 2002; Chmielowiec-Korzeniowska *et al.*, 2018).

Conclusions

Animal production is an occupational environment with scientific evidence about occupational exposure to microbial agents, and more specifically to fungi. The available research is scarce, nevertheless all the information gathered with this review highlights the importance of monitor this type of environment and implement protocols to assess fungal burden, specially *Aspergillus* sections, since they can cause adverse health problems due to their pathogenic and toxigenic potential.

Introduction

Bioaerosols are microbial fragments, constituents of cells and airborne biological particles that can consist of fungi, bacteria, pollen, fragments, constituents, particulate matter (PM₁₀), and by-products of cells, that may be viable or nonviable (Dowd and Maier, 1999; Douwes *et al.*, 2003; Viegas and Gomes, 2014; Pearson *et al.*, 2015). Exposure to bioaerosols can lead to a number of pathologies, such as: non-allergic irritative reactions (upper and lower respiratory tracts, asthma, contact dermatitis), inflammatory (chronic bronchitis), allergic or immunoallergic reactions (rhinitis, sinusitis, allergic asthma, hypersensitive pneumonitis, and organic dust toxic syndrome), and infections like invasive aspergillosis in immunosuppressed individuals (Bünger *et al.*, 2000; Douwes *et al.*, 2003; Viegas *et al.*, 2015).

Microbiological exposures associated with waste can occur indoors, where waste is stored, or outdoors during its collection and it may be influenced by the process of sorting, transfer or cleaning (Wouters *et al.*, 2000; Lavoie and Dunkerley, 2002; Abou-Elwafa and El-Bestar, 2014).

In this type of highly contaminated environment, one of the most prevalent genera is *Aspergillus* spp. (Viegas *et al.*, 2017b). However, there are a few more genera/species that are also considerably prevalent such as *Aureobasidium pullulans*, *Epicoccum nigrum*, *Fusarium sambucinum*, *Beauveria bassiana*, *Rhizopus stolonifer*, *Phoma*, *Absidia*, *Mucor*, *Rhizopus*, *Penicillium*, and yeasts (Grisoli *et al.*, 2009).

In addition, it is important to highlight that workers may be exposed to the same potential hazards as the general population, although exposure and danger may be different due to waste disposal by workers and, as a result, proximity to pollution sources and a more contaminated indoor environment (Rushton, 2003).

It has been shown that waste management releases airborne microorganisms and bioaerosols into the atmosphere around waste facilities (Viegas and Gomes, 2014) and that temperature, relative humidity, and wind speed affect concentrations and viability of airborne microorganisms (Jones and Harrison, 2004). Consequently, this type of industry and facilities are considered critical in terms of occupational exposure to fungal contamination (Heinonen-Tanski *et al.*, 2009; Hameed and El Gendy, 2013) as they provide optimal conditions for fungal growth (Thirumala *et al.*, 2012).

The installation of a central ceiling diffuser to provide downstream fresh air, as well as to keep workers' breathing zones free of pollutants, and cleaning procedures are preventive measures that are usually applied in sorting cabinets (Marchand *et al.*, 1995). However, it's important to consider that waste-sorting it's crucial to maximize recycling (Viegas *et al.*, 2020) and that additional monitoring should be performed to evaluate the workers exposure (Marchand *et al.*, 1995) and to solve remaining contamination and, consequently, exposure problems.

Materials and Methods

This study is based on a research of the available information/data on fungal occupational exposure in waste industry, published between 1st of January 2010 and 31st of December 2019, following the PRISMA methodology. The databases chosen were b-on, PubMed and WOS and the keywords used were "fungi", "occupational exposure", and "waste industry". Searches were carried out in English. However, since the last two databases led to a small number of results (<20 papers), and that the papers were the same in b-on results, those databases were excluded, and only b-on results were considered to this study. This search led to nearly 1010 papers in b-on database. Articles that did not meet the inclusion criteria were excluded from further analysis (but some of them were used for introduction and discussion) (Table 1) (Fig. 1).

Results

Among the 20 papers included in this study (Table 2), analysis was performed regarding the occupational environment studied, which country belongs the industry, sampling methods applied, the environmental matrix which assays were applied, and the most prevalent fungal species found.

Table 1 Inclusion and exclusion criteria

Inclusion Criteria	Exclusion Criteria
Articles published in the English language;	Articles published in other languages
Articles published from 1st of January 2010 to 31st of December 2019	Articles published prior to 1st of January 2010
Articles related to fungi assessment in waste industry	Articles related exclusively to biologic samples from patients
Original scientific articles on the topic	Abstracts of congress, reports, reviews/state of the art articles
Articles published in any country	

**Fig. 1** PRISMA methodology of selection of papers.

Regarding the environmental matrix, most studies (14 out of 20) presented air as the only type of sample (Issever *et al.*, 2011a,b; Burkowska *et al.*, 2014; Taylor *et al.*, 2015b; Hameed *et al.*, 2015; Černá *et al.*, 2017; Madsen *et al.*, 2016; Bonifait *et al.*, 2017; Gladding and Gwyther, 2017; Wolany and Płaza, 2017; Afsharnia *et al.*, 2018; Mbareche *et al.*, 2018; Madsen *et al.*, 2019; Line *et al.*, 2019), the remaining studies presented air samples in parallel with samples collected by passive sampling methods (Viegas and Gomes, 2014; Taylor *et al.*, 2015a; Viegas *et al.*, 2015, 2016, 2017b).

In most studies (7 out of 20), the air samples were only collected by impaction methods (Issever *et al.*, 2011a,b; Burkowska *et al.*, 2014; Taylor *et al.*, 2015a,b; Wolany and Płaza, 2017; Afsharnia *et al.*, 2018), some other (3 out of 20) used only impingement methods (Hameed *et al.*, 2015; Gladding and Gwyther, 2017; Mbareche *et al.*, 2018) and a few others (4 out of 20) used only filtration methods (Viegas *et al.*, 2017a; Černá *et al.*, 2017; Madsen *et al.*, 2016; Line *et al.*, 2019). The remaining studies combined either two active sampling methods (2 out of 20) (Bonifait *et al.*, 2017; Madsen *et al.*, 2019), two active sampling methods and one passive sampling method (1 out of 20) (Viegas *et al.*, 2017a,b) or one active sampling method and one passive sampling method (3 out of 20) (Viegas and Gomes, 2014; Viegas *et al.*, 2015, 2016). The passive sampling used in those six studies was swabbing (Viegas and Gomes, 2014; Taylor *et al.*, 2015a,b; Viegas *et al.*, 2015, 2016, 2017b), collected compost (Taylor *et al.*, 2015a,b), and filters from the air conditioning system of forklifts (Viegas *et al.*, 2017b).

Concerning the methods of fungal identification, most studies (12 out of 20) used only culture-based methods (Issever *et al.*, 2011a,b; Burkowska *et al.*, 2014; Taylor *et al.*, 2015a,b; Hameed *et al.*, 2015; Černá *et al.*, 2017; Madsen *et al.*, 2016; Gladding and Gwyther, 2017; Wolany and Płaza, 2017; Afsharnia *et al.*, 2018; Madsen *et al.*, 2019). Additionally, some studies (6 out of 20) combined culture-based methods with molecular tools (Viegas and Gomes, 2014; Viegas *et al.*, 2015, 2016; Bonifait *et al.*, 2017;

Table 2 Papers included in the review

<i>Setting</i>	<i>Environmental Matrix</i>	<i>Sampling</i>	<i>Assays Applied</i>	<i>Results (Most prevalent fungi found – Genera/species)</i>	<i>Country</i>	<i>Reference</i>
Occupational exposure -Respiratory functions of the people working in solid waste storage centers	Air	Impaction	Culture-based methods	<i>Culture-based methods:</i> Aspergillus sp and Cladosporium sp	Turkey	Issever <i>et al.</i> (2011a)
Fungal Flora at Solid Waste Storage Centers and Their Potential Allergenic Effects on the Workers	Air	Impaction	Culture-based methods	<i>Culture-based methods:</i> Aspergillus sp. and Cladosporium sp.	Turkey	Paper <i>et al.</i> (2011)
Exposure of Workers of Municipal Landfill Site to Bacterial and Fungal Aerosol	Air	Impaction	Culture-based methods	<i>Culture-based methods:</i> Penicillium spp., Cladosporium spp. Alternaria spp. and Aspergillus spp.	Poland	Burkowska <i>et al.</i> (2014)
Fungal contamination in two plants handling solid waste management – one waste sorting plant and one incineration plant	Air Surface (swabs)	Impaction and swabbing	Culture-based methods Molecular tools Particulate matter assessment	- <i>Waste sorting plant</i> <i>Culture-based methods:</i> <i>Air and surface samples:</i> Aspergillus sections Nigri, Fumigati, and Flavi <i>Molecular Tools (qPCR):</i> No species amplified - <i>Incineration plant</i> <i>Culture-based methods:</i> Air samples - Penicillium sp. and Aspergillus sections Fumigati and Flavi Surface samples - Penicillium sp. and Aspergillus sections Fumigati and Nigri <i>Molecular Tools (qPCR):</i> No species amplified	Portugal	Viegas and Gomes (2014)
Microbial contamination within working environments of different types of composting plants	Air Surface (swabs) Compost	Impaction	Culture-based methods	<i>Culture-based methods:</i> Aspergillus fumigatus, Cladosporium (C. cladosporioides, C. herbarum, C. macrocarpum), and Rhizopus oryzae	Poland	Taylor <i>et al.</i> (2015a)
Occupational risk of exposure to biological agents in a waste packaging glass sorting plant	Air	Impaction	Culture-based methods	<i>Culture-based methods:</i> Penicillium spp.	Portugal	Taylor <i>et al.</i> (2015b)

Table 2 Continued

Setting	Environmental Matrix	Sampling	Assays Applied	Results (Most prevalent fungi found – Genera/species)	Country	Reference
Fungal burden in waste industry: an occupational risk to be solved	Air Surface (swabs)	Impaction and swabbing	Culture-based methods Molecular Tools	<i>Before cleaning</i> Culture-based methods: Air (indoor): <i>Penicillium</i> sp., <i>A. fumigatus</i> , <i>A. niger</i> , Surface: <i>A. niger</i> , <i>E. herbarium</i> Air (outdoor): <i>Penicillium</i> sp., <i>A. fumigatus</i> , <i>A. niger</i> Molecular Tools (qPCR): <i>A. fumigatus</i> After cleaning Culture-based methods: Air (indoor): <i>A. niger</i> complex and <i>Penicillium</i> sp. Surface: <i>A. niger</i> complex and <i>Ulocladium</i> sp. Air (outdoor): <i>A. fumigatus</i> complex Molecular Tools (qPCR): <i>A. fumigatus</i>	Portugal	Viegas <i>et al.</i> (2015)
Airborne fungal pollution at waste application facilities	Air	Impingement	Culture-based methods	<i>Culture-based methods:</i> <i>Aspergillus</i> sections <i>Fumigatus</i> and <i>Flavi</i> , <i>Penicillium</i> spp. and <i>Cladosporium</i> spp.	Egypt	Hameed <i>et al.</i> (2015)
Analysis of surfaces for characterization of fungal burden waste management plants and wastewater treatment plants	Air Surface (swabs)	Impaction and swabbing	Culture-based methods Molecular tools	<i>Culture-based methods:</i> <i>Cladosporium</i> sp., <i>Penicillium</i> sp., <i>A. fumigatus</i> complex, <i>A. versicolor</i> complex and <i>A. flavus</i> complex. Molecular Tools (qPCR): <i>A. flavus</i> complex (toxigenic strains), <i>A. fumigatus</i> complex and <i>Stachybotrys chartarum</i>	Portugal	Viegas <i>et al.</i> (2016)
Exposure to airborne fungi during sorting of recyclable plastics in waste treatment facilities	Air	Filtration	Culture-based methods	<i>Culture-based methods:</i> <i>Penicillium</i> spp. and <i>Aspergillus</i> spp.	Czech Republic	Černá <i>et al.</i> (2017)
Waste Workers' Exposure to Airborne Fungal and Bacterial Species in the Truck Cab and During Waste Collection	Air	Filtration	Culture-based methods	<i>Culture-based methods:</i> <i>Penicillium</i> spp.	Denmark	Madsen <i>et al.</i> (2016)

Workers' exposure to bioaerosols from three different types of composting facilities - domestic, manure, carcass	Air	Impingement and impaction	Culture-based methods Molecular Tools	<i>Culture-based methods:</i> <i>Thermophilic actinomycetes</i> and <i>A. fumigatus</i> <i>Molecular Tools (qPCR):</i> <i>Penicillium</i> and <i>A. fumigatus</i>	Canada	Bonifait et al. (2017)
Occupational exposure to airborne fungal contamination of forklift drivers in waste sorting facilities	Filters from the air conditioning system of forklifters	Filtration	Culture-based methods Molecular tools Mycotoxins analysis Cytotoxicity assay	<i>Culture-based methods:</i> <i>Aspergillus</i> sections <i>Circumdati</i> and <i>Nigri</i> . <i>Molecular Tools (qPCR):</i> <i>Aspergillus</i> section <i>Fumigati</i>	Portugal	Viegas et al. (2017a)
<i>Aspergillus</i> spp. prevalence in different Portuguese occupational environments - waste management plants and wastewater treatment plants	Air Surface (swabs)	Impingement, impaction and swabbing	Culture-based methods Molecular Tools	<i>Culture-based methods:</i> <i>Aspergillus</i> sections <i>Nigri</i> , <i>Fumigati</i> and <i>Flavi</i> <i>Molecular Tools (qPCR):</i> <i>Aspergillus</i> section <i>Fumigati</i>	Portugal	Viegas et al. (2017b)
Potential release of bioaerosols from containers as a result of reduced frequency residual waste collections	Air	Impingement	Culture-based methods	<i>Culture-based methods:</i> <i>A. fumigatus</i> and Thermotolerant fungi (species unidentified)	UK	Gladding and Gwyther (2017)
Characteristics of airborne fungi in some Polish wastewater treatment plants	Air	Impaction	Culture-based methods	<i>Culture-based methods:</i> <i>C. Cladosporioides</i>	Poland	Wolany and Plaza (2017)
Identifying and Determining Dispersion Boundary Bio-aerosols of Bacterial and Fungal Pathogens from Municipal Waste Collection Containers	Air	Impaction	Culture-based methods	<i>Culture-based methods:</i> <i>Aspergillus</i> spp., Yeast and <i>Alternaria</i> spp.	Iran	Afsharnia et al. (2018)
Fungal bioaerosols in biomethanization facilities	Air	Impingement	Molecular Tools (qPCR and NGS)	<i>Molecular Tools (qPCR):</i> <i>Penicillium</i> spp., <i>Aspergillus</i> spp. and <i>Aspergillus fumigatus</i>	Canada	Mbareche et al. (2018)
Expanded cardboard waste sorting and occupational exposure to microbial species	Air	Filtration and impaction	Culture-based methods	<i>Culture-based methods:</i> <i>Penicillium commune</i> , <i>P. italicum</i> and <i>P. brevicompactum</i>	Denmark	Madsen et al. (2019)
Occupational exposure during treatment of offshore drilling waste and characterization of microbiological diversity	Air	Filtration	Culture-based methods	<i>Quantitative Results:</i> 20 CFU/mL	Norway	Line et al. (2019)

Viegas *et al.*, 2017a,b), and the remaining two studies used either only molecular tools (Mbareche *et al.*, 2018), or culture based methods achieving only quantification of fungal contamination (Line *et al.*, 2019).

Through culture-based methods, *Aspergillus* spp. and *Penicillium* spp. were the most commonly found fungi (18 out of 20) (Issever *et al.*, 2011a; Burkowska *et al.*, 2014; Viegas and Gomes, 2014; Taylor *et al.*, 2015a,b; Viegas *et al.*, 2015; Hameed *et al.*, 2015; Černá *et al.*, 2017; Madsen *et al.*, 2016; Viegas *et al.*, 2016; Bonifait *et al.*, 2017; Viegas *et al.*, 2017a,b; Gladding and Gwyther, 2017; Afshamia *et al.*, 2018; Mbareche *et al.*, 2018; Madsen *et al.*, 2019). However, some studies presented different fungi with a considerable prevalence like *Cladosporium* spp. (Issever *et al.*, 2011a,b; Burkowska *et al.*, 2014; Taylor *et al.*, 2015a; Hameed *et al.*, 2015; Viegas *et al.*, 2016; Wolany and Plaza, 2017), *Rhizopus* spp. (Taylor *et al.*, 2015a), and *Alternaria* spp. (Burkowska *et al.*, 2014; Afshamia *et al.*, 2018).

When applying molecular tools the most prevalent genera detected (5 out of 20) were *Aspergillus* spp. (Viegas *et al.*, 2015, 2016; Bonifait *et al.*, 2017; Viegas *et al.*, 2017a,b), and two studies had another fungal species such as *Stachybotrys chartarum* (Viegas *et al.*, 2016) and *Penicillium* spp. (Bonifait *et al.*, 2017).

A few studies (10 out of 20), identified *Aspergillus* spp. to the section level (Viegas and Gomes, 2014; Taylor *et al.*, 2015a; Viegas *et al.*, 2015; Hameed *et al.*, 2015; Viegas *et al.*, 2016; Bonifait *et al.*, 2017; Viegas *et al.*, 2017a,b; Gladding and Gwyther, 2017; Mbareche *et al.*, 2018). The most prevalent *Aspergillus* sections were *Fumigati* (Viegas and Gomes, 2014; Viegas *et al.*, 2015; Hameed *et al.*, 2015; Viegas *et al.*, 2016; Bonifait *et al.*, 2017; Viegas *et al.*, 2017a,b; Gladding and Gwyther, 2017), followed by *Nigri* (Viegas and Gomes, 2014; Viegas *et al.*, 2015, 2017a,b) and *Flavi* (Viegas and Gomes, 2014; Abdel Hameed *et al.*, 2015; Viegas *et al.*, 2016, 2017b).

Discussion

It is well known that waste management has an enormous influence as a release agent of a wide range of different microbiological agents (Pillai and Ricke, 2002; Viegas and Gomes, 2014). Fungi can affect human health in several ways that result in health outcomes such as infections, allergic reactions, irritation and toxic reactions (Fischer and Dott, 2003; McGinnis, 2004; Viegas *et al.*, 2016). Studies to perform exposure assessment to fungi in waste handling are increasing in several countries (Nielsen *et al.*, 1995; Poulsen *et al.*, 1995; Wouters *et al.*, 2006; Lavoie *et al.*, 2006; Park *et al.*, 2011; Madsen *et al.*, 2016), and the 20 papers used in this review are following this trend.

Regarding the analyzed papers, as previously reported, most of them (19 out of 20) used air as an environmental matrix, being impaction the most common sampling method (taking into account studies with one and more sampling methods). Since this method relies only on culture based-methods, this can be a feature from this sampling approach since the viability of micro-organisms can affect their inflammatory and/or cytotoxic potential (Croston *et al.*, 2016), and thus it is possible to conclude about the inflammatory potential that varies according to the microbial composition of the bioaerosol (Timm *et al.*, 2009).

Impaction samplers collect particles from air with a specific flow rate and place them on a collecting surface such as Petri dishes containing agar medium (Institute APT, 1980). However, it is important to highlight that this sampling method has some disadvantages, since only assesses organisms that are culturable, that represent only one or two percent of the total air spore. Another disadvantage are the fact that in indoor environments the air is not uniform in space or time, it is always affected by the type of activity (Stellman, 1998) and its intensity, and that the high velocity of the air flow may result in the loss of some particles (Institute APT, 1980).

Taking all that into account, it is important to consider the use of passive sampling methods as a complement to active sampling methods. As previously reported, some studies (5 out of 20) combined an active sampling method (impaction) with a passive sampling method (surface samples (swabs)). Those two methods combined, increase the sensitivity of the assessment and eliminate the described disadvantages of the impaction samplers (Viegas *et al.*, 2016).

In this type of industry, there are passive sampling methods other than swabbing that can be useful to provide a more accurate exposure assessment to fungal contamination. Protection devices used by workers, such as Filtering Respiratory Protective Devices (FRPD), are used as an individual protection for workers and they can replicate the real scenario of exposure by inhalation since the FRPD is covering the workers airways (Viegas *et al.*, 2020). Therefore, the results obtained by the FRPD are similar to the results obtained in studies that combined active (air sampling) and passive (surface sampling) sampling methods (Viegas *et al.*, 2015, 2017a, 2020). Furthermore, FRPD can be suggested and desirable as a sampling method, since it has the ability to collect the sample of a wider period of time, just like any other passive sampling method, and also because it allows the combination of different approaches such as culture-based methods and molecular tools, to complement the study and the results (Viegas *et al.*, 2020).

Most papers (12 out of 20) used only culture-based methods to perform fungal identification, however, it is important to notice that this method has its own disadvantages such as how the growth speed and requirements of different fungal species affect other species in mixed cultures. For instance, the fast growth of a specific species may cause its overgrowth and consequently a chemical competition that can inhibit the growth of other species (Viegas *et al.*, 2015) and subsequently lead to lack of accuracy in the study results. Those reasons support the use and combination of culture-based methods and molecular tools, as seen in some papers (6 out of 20) of this study. Molecular tools detain some characteristics that allows them to be more efficient than other methods such as its accuracy, speed, it's extreme analytical sensitivity of detection and the fact that allows the detection and identification of dead or dormant microorganisms, as well as toxigenic strains from specific fungal species (Amann *et al.*, 1995; MacNeil *et al.*, 1995; Viegas *et al.*, 2015). Therefore, the complement between culture-base methods and molecular tools should always be recommended.

In both methods, as previously mentioned, *Aspergillus* spp. appeared with the highest prevalence and that is a big concern in terms of occupational health since it has been reported an increase of infections caused by opportunistic *Aspergillus* in immunocompromised patients, and also an increase of antifungal resistance, both in the clinical and in the environment (Fairlamb *et al.*, 2016; Nature Microbiology, 2017; Viegas *et al.*, 2020). Another fact that represents a high occupational risk is that several *Aspergillus* species have a pathogenic potential (Varga *et al.*, 2015; Viegas *et al.*, 2018, 2020) such as *A. flavus*, *A. niger*, *A. terreus*, *A. versicolor*, *A. calidoustus*, and *A. nidulans* that can cause several health conditions like allergic bronchopulmonary aspergillosis, chronic pulmonary aspergillosis and invasive aspergillosis (Lamoth, 2016). Consequently, measures should be taken to implement and standardize the proper assessment of the prevalence of this genera, as recommended in Viegas *et al.* (2017b).

Conclusions

Although waste industry is an occupational environment with an increasing scientific evidence about occupational exposure to microbial agents, the information gathered with this review highlights the importance of monitor and implement protocols to assess fungal burden, focusing on *Aspergillus* species.

Sources of Mold and Mold-Derived Fragments or Metabolites and Elevated Mold Exposure

Fungi normally present in indoor environments represent a mixture of species (reviewed in Adams *et al.*, 2013; Du *et al.*, 2021; Haleem Khan and Mohan Karuppayil, 2012). Under normal circumstances where obvious indoor fungal contamination is absent, the fungal propagules that predominate in indoor environments arise from three primary reservoirs: (1) the phylloplane/phyllosphere (the ecology of the surface of leaves considered to be a habitat, especially for yeasts and filamentous fungi), (2) the pedosphere (the outermost layer of the earth that is composed of soil and subject to environmental processes), and (3) the dermatophane (skin surface) (Adams *et al.*, 2013).

Phylloplane fungi comprise an ecologically similar grouping of unrelated, dry-spored fungal taxa that inhabit plant leaf surfaces (Levetin and Dorsey, 2006). In northern regions, phylloplane taxa predominate in the aerospora during the growing season. Owing to their abundance in the outdoor air, aerosols derived from these fungi, including spores, hyphal fragments and cellular debris, filter into indoor environments through normal activity and openings in the building envelop, primarily windows and ventilation systems. Characteristic taxa in this category include certain species of *Aspergillus*, *Alternaria*, *Cladosporium*, *Penicillium*, rust and smuts, agarics, and brackets (Basidiomycetes).

Fungi originating from soil reservoirs also commonly are found in indoor environments (Frac *et al.*, 2018). These mostly wet-spored fungi may enter buildings on footwear, particularly common where footwear is not removed upon entry into a building. Alternatively, soil containing fungal material may become aerosolized during building works or heavy excavation activities and these dust aerosols may be transported indoors on air currents or via human movements or actively through the actions of mechanical air handling systems. Taxa in this category include species of *Aspergillus*, *Acremonium*, *Fusarium*, *Trichoderma* and *Penicillium*. Demolition, gardening, sweeping and strong winds will also contribute to the indoor environment mycoflora. The release of fungal spores is most often seasonal. Molds (filamentous fungi) growing on plant surfaces show peak airborne concentrations seasonally in accordance with the life cycles of the plants. In northern, temperate climates, airborne levels of these molds decrease substantially during the winter.

Virtually all buildings contain molds, but some are moldier than others due to a variety of factors including water ingress, damp, wet cells and the annual hygrothermal performance of buildings (reviewed in Du *et al.*, 2021). Indoor molds can be remarkably tolerant of dry conditions but none can live without moisture. Excessively moldy buildings generally have a source of moisture leading to unusually heavy mold growth. The source of the moisture may be a damp or flooded basement, a dripping pipe, a roof in need of repair or some other fairly obvious cause. In most cases the mold can be seen growing on walls or other materials in contact with the moisture. Sometimes the moisture can occur inside walls and not be apparent (termed interstitial mold). A common but not obvious cause of moisture in cold climates is condensation. Severely moldy buildings may have a musty smell, but not necessarily. Sometimes the only sign of a problem is persistent poor health of the occupants, such as headaches, nausea, respiratory symptoms, for example, exacerbation of asthma.

Like other *Aspergillus* species, *A. fumigatus* has a worldwide distribution (Ashu *et al.*, 2017; Sewell *et al.*, 2019). This probably results from the production of numerous airborne conidia, which easily disperse by air movements and possibly by insects. The composition of the atmosphere has a great impact on mold growth, with humidity being the most important variable. *A. fumigatus* grows optimally with water activity (a_w) between 0.86 and 0.96. The optimum temperature for *A. fumigatus* to grow is 37°C, but fungal growth can be observed at temperatures ranging from 12°C to 48°C.

This review will focus primarily on where *Aspergillus* is found in built environments. It is present in air, and in dust found in infrequently-cleaned places, particularly attics and cellars, on potted ornamental plants and flowers, on shutters, carpets and in vacuum cleaners (reviewed in Mousavi *et al.*, 2016). This organism has also been identified in many food types, especially spices, tea, biscuits and fruits. Some of these reservoirs are not limited to community indoor environments and are also found in hospitals and workplaces. Important sources of *Aspergillus* in outdoor environments include soil, plant debris, rotten vegetation, manure, sawdust litter, bagasse litter, animal feed, bark chippings, on animals. Water may be an alternative source of *Aspergillus* conidia or where *Aspergillus* biofilms are formed in water distribution systems (reviewed in Richardson and Rautemaa-Richardson, 2019).

What is Aspergillosis?

Aspergillosis is seen worldwide (see “Relevant Websites section”). Manifestations include allergic aspergillosis (rhinosinusitis and bronchopulmonary, often complicating asthma and cystic fibrosis) (estimated number of cases > 10 million), chronic pulmonary aspergillosis (~3 million), invasive aspergillosis (incidence > 300,000 annually), and superficial disease (notably keratitis, otomycosis, and trauma or burn wound infections) (Kosmidis and Denning, 2015).

The genus *Aspergillus* includes over 300 species, divided into 22 sections (Gautier *et al.*, 2016). Around 20 species have so far been reported as causative agents of opportunistic infections in humans, although many cryptic species are now implicated, so the term complex is added to species names, unless definitive identification has been conducted. Among these, *Aspergillus fumigatus* is the most commonly isolated species, followed by *A. flavus* and *A. niger*. *A. nidulans*, *A. terreus*, *A. calidoustus*, and *A. versicolor* are among the other species less commonly isolated. In respiratory samples from patients with chronic and allergic forms of pulmonary aspergillosis, fifty-six (2.5%) isolates were identified as *Aspergillus* cryptic species by sequencing of ITS, BenA and CalM gene loci (Bongomin *et al.*, 2018). Common cryptic species were *Aspergillus montevidensis*, *A. sydowii* and *A. calidoustus*. It is important to identify these species because of the high frequency of antifungal drug-resistance.

Is Aspergillosis Community Acquired or a Hospital-Associated Infection?

Differentiation between nosocomial and community aspergillosis is important for investigation, exposure pathways and prevention, and to understand whether the indoor environment is a source of exposure (reviewed in Nicolle *et al.*, 2011). Nosocomial (hospital-acquired) infections require appropriate infection control measures to avert additional cases. Nosocomial invasive aspergillosis occurs during hospitalization or is caused by *Aspergillus* acquired during hospital stay. Such infections should not be evident when patients are admitted to the hospital. Furthermore, the definition of nosocomial aspergillosis is based on epidemiological criteria, such as the time lapse between admission and onset, or microbiological criteria. This definition might be difficult to apply to invasive aspergillosis which often afflicts patients with severe immunosuppression or who have undergone solid organ transplantation. Identification of the source may be difficult which could either be outside or inside the hospital. Another significant issue is the lack of valid and reproducible data on the incubation period. The incubation duration of IA is influenced by different individual, environmental and mycological determinants, including the severity of immunosuppression (for example, neutropenia), the aggressiveness of the *Aspergillus* strain and air quality. A better understanding of early events related to invasive aspergillosis onset will help to prevent this disease for which the prognosis still remains very poor.

Investigation of Indoor Biotic Fungal Communities

The investigation of indoor microbial ecology has been based primarily on culture, but more recently it has been facilitated by nucleic acid sequence-based methods, (Adams *et al.*, 2013; Vesper *et al.*, 2007). Together, these approaches have identified fungi that grow indoors when moisture is available. From recent studies that have relied on nucleic acid amplification techniques to assess total fungal assemblages it is clear that fungi in settled dust are diverse, that variation between buildings can be large and fluctuate with the outdoor air, and that, as a result, there may not be a typical profile of indoor fungi that distinguishes different types of buildings (reviewed in Rintala *et al.*, 2012; Du *et al.*, 2021).

Ongoing research in Norway has used next generation sequencing to decipher the mycobiome of indoor environments (See Relevant Websites Section). The project has combined air sampling with high-throughput DNA sequencing (HTS) and qPCR. HTS is particularly useful in characterizing the microbial communities present in environmental samples, for example, dust and air from buildings. It was found that regional climate factors significantly affected both outdoor and indoor mycobiomes, owing to an ingress of spores from outdoor sources. Furthermore, features of the buildings studied and their occupants also influenced the indoor mycobiomes, in particular, the detection of *Penicillium*, *Aspergillus* and *Botrytis* found colonizing building materials. In contrast, outdoor mycobiomes were distinctly enriched in rock-inhabiting fungi, which include lichen-forming fungi (Lecanorales) and black fungi (Chaetothyriales and Capnodiales). The investigators anticipate that the project will have a relevant impact on related scientific areas (microbiology of the built environment, fungal ecology and human exposure), as well as on commercial activities related to building microbiology and material biodeterioration.

An extensive survey by Visagie and colleagues highlighted that xerophilic *Aspergillus* species (those species that thrive in dry environments and have a low water requirement) are one of the dominant genera of the indoor environment (Visagie *et al.*, 2017). A survey of xerophilic fungi isolated from Canadian and Hawaiian house dust resulted in the isolation of 1039 strains; 296 strains belonged to *Aspergillus* and represented 37 species. *Aspergillus* sect. *Aspergillus* (formerly called *Eurotium*) was one of the most predominant groups from house dust with nine species identified. Among all strains, two new species were found: *A. mallochii* and *A. megasporus*.

General Considerations of *Aspergillus* Growth and Proliferation

To understand whether the indoor environment is a conducive place for *Aspergillus* to grow it is important to review the growth requirements and ecological niches where *Aspergillus* has been found to understand exposure pathways.

Nutrients

Aspergillus assimilates preformed organic matter; carbohydrates being the preferred carbon source (Rhodes, 2006). *Aspergillus* can readily absorb and metabolize a variety of soluble carbohydrates, such as glucose, xylose, sucrose, and fructose. It is characteristically well suited to using insoluble carbohydrates such as starches, cellulose, and hemicelluloses, as well as very complex hydrocarbons such as lignin. Saprophytic fungi, such as *Aspergillus* obtain their food from dead organic material; parasitic fungi do so by feeding on living organisms (usually plants), thus causing disease.

Water

Most fungi require very high water availability and rapidly dry out, or senesce, under dry conditions (Andersen *et al.*, 2011). However, fungi are also able to tolerate much lower water availability than other organisms. The most xerophilic organism, *Xeromyces bisporus*, can grow at a water activity (a_w) of 0.62, while many other species such as *Eurotium*, *Aspergillus*, *Wallemia*, and *Penicillium* commonly contaminate low water activity environments (a_w 0.75–0.90). Xerophilic molds are also extremely common in indoor environments but are often neglected and not found if the detection method uses high water activity isolation media. Some species of *Aspergillus*, for example, *A. penicilloides*, is a halophyte (Nazareth and Gonsalves, 2014). This species requires a high salt-content culture medium to support its growth.

pH

For most fungi, a pH range of 5.5–6.5 seems to be suitable for their maximum growth and sporulation, but the hydrogen environment of fungi is difficult to study because they change the pH of their environment as they grow. A typical example is *A. niger*, which produces citric and other organic acids and thus lowers the pH of the substrate. Generally speaking, fungi can tolerate a wide range of pH.

Oxygen

Aspergillus has the capacity to function facultatively under aerobic and anaerobic conditions. Oxygen is used for oxidative metabolism, to generate energy. However, it is also essential for the biosynthesis of sterols, unsaturated fatty acids, and some vitamins.

Temperature

Aspergillus species can normally tolerate the range of temperature of the environment where they are found growing. However, active growth will usually be associated with a limited range of temperatures. There are different definitions of temperature requirements, but those fungi that grow between 15°C and 35°C are usually called mesophilic, and those growing above this range are termed thermophilic. Many *Aspergillus* species are thermotolerant. Temperature affects specific growth rate, and sporulation. High or low temperatures may cause the *Aspergillus* to enter dormancy.

Light

Light does not play a major part in the metabolism and growth of fungi. For the cultivation and sporulation of common species, light seems not to be a limiting factor. Most fungi, including *Aspergillus* species develop well in the dark in outdoor and indoor environments. UV radiation can reduce the viability of conidia, especially in air. It has been found that 600 mWs/cm² of UV at 260 nm could potentially be used for the inactivation of *Aspergillus niger*, *Penicillium citrinum*, and *Cladosporium cladosporioides* (Levetin *et al.*, 2001). The study demonstrated the effectiveness of UV is where levels of fungi growing on insulation within air-handling units (AHUs) in an office building and levels of airborne fungi within AHUs were measured before the use of germicidal UV light and again after 4 months of operation. The fungal levels following UV operation were significantly lower than the levels in control AHUs.

Where Does *Aspergillus* Proliferate?

Decaying vegetation is the primary ecological niche of *Aspergillus fumigatus* (Rhodes, 2006). The organism also lives in outdoor soil, and rural areas are a major source of contamination. Other reservoirs are compost heaps, hay barns and bird droppings and a variety of indoor biotic environments. Some of these ecological niches are examined further.

Soil

Aspergillus species appears to spend most of its life growing as a saprophyte in the soil, where it plays an important role as a nutrient recycler, supported by plant and animal debris. The ability of *Aspergillus* to survive in harsh conditions allows it to easily

out-compete other organisms for substrates in the soil or on plants. The fungus overwinters either as mycelium or as resistant structures known as sclerotia, for example, *A. flavus*. The sclerotia either germinate to produce additional hyphae or they produce conidia (asexual spores), which can be further dispersed in the soil and air.

Water

Fungi in drinking water may alter the taste and odors of the water. Health problems are possible, including mycotoxin exposure, direct infection and allergy. More studies are needed on this subject. Surveys of fungi in drinking water have recovered many different taxa, including *Aspergillus* (reviewed in [Richardson and Rautemaa-Richardson, 2019](#)). Contamination tends to arise from surface reservoirs and not from deep ground wells. This variation is often attributed to factors such as raw water source (surface versus well), water temperature patterns, treatment patterns and maintenance of distribution systems. Additionally, it was reported that fungi can pass through treatment processes by means of leaks in the system, or from air in contact with water stored in distribution system reservoirs, and can even survive water disinfection with chlorine.

Water-Damaged Building Materials

Andersen and colleagues estimated the qualitative and quantitative diversity of fungi growing on damp or water-damaged building materials ([Andersen et al., 2011](#)). An additional aim of the study was to determine if associations existed between the most commonly found fungal species and different types of building fabric. More than 5300 surface samples were taken by means of V8 contact plates from materials with visible fungal growth. Fungal identifications and information on building material components were analyzed using multivariate statistic methods to determine associations between fungi and material components. The results confirmed that *Penicillium chrysogenum* and *Aspergillus versicolor* were the most common fungal species in water-damaged buildings. The results also showed *Chaetomium* spp., *Acremonium* spp., and *Ulocladium* spp. to be very common on damp building materials. Analyses show that associated mycobiotas exist on different building materials. Interestingly, associations were found between *Aspergillus fumigatus*, *A. melleus*, *A. niger*, *A. ochraceus*, *Chaetomium* spp., *Mucor racemosus*, *Mucor spinosus*, and floor-related materials.

Colonization of Buildings and Building Fabric

Many manufactured products are susceptible to mold attack. Painted walls, particularly in humid places such as showers, can become overgrown by certain fungi, notably species of *Phoma* and *Exophiala*. Wallpapers also serve as a source of nutrition for some molds. Commonly cited are *Scopulariopsis* species which have been reported to grow on wallpapers containing arsenic pigments and to release very poisonous gases. With modern wallpaper pigments, which contain no arsenic, this cannot happen.

Modern heating systems are designed to remove humidity from buildings, creating opportunities for xerophiles to dominate indoor fungal communities. Due to their xerophilic physiology species of section *Aspergillus* makes them significant for the built environment. Here, these species are among the primary colonizers of building materials ([Visagie et al., 2017](#)). Also of concern is the growth of these fungi in museums or libraries on historic artefacts such as books, carpets or paintings (reviewed in [Visagie et al., 2017](#)). They also commonly grow on/in leather, dust, softwood, a variety of textiles and even dried specimens in herbaria.

Haleem Khan and colleagues answered this question within the context of the spectrum of molds found colonizing a wide range of damp building materials (reviewed in [Haleem Khan and Mohan Karuppayil, 2012](#)). A key feature of many of the studies is an understanding that fungi are able to grow on almost all natural and synthetic materials, especially if they are hygroscopic or wet. Inorganic materials get frequently colonized as they absorb dust and serve as good growth substrates for *Aspergillus fumigatus* and *Aspergillus versicolor*. Wood is highly vulnerable to fungal attack. *Cladosporium* and *Penicillium* (*P. brevicompactum* and *P. expansum*) colonize wooden building materials. Kiln dried wood surfaces are more susceptible to fungi. Acylated wooden furniture, wood polyethylene composites, plywood and modified wood products are susceptible to colonization by *Aspergillus*, *Trichoderma* and *Penicillium*.

Inner wall materials used in buildings, such as prefabricated gypsum board, highly favors the growth of *Stachybotrys chartarum* especially when it becomes damp due to it be hygroscopic but interestingly, *Aspergillus fumigatus* does not appear to be a primary colonizer of gypsum board. Paper and glue used in indoor surfaces are very good growth substrates for most of the indoor fungi. Fiber glass insulation and ceiling tiles support the growth of a number of fungi, including *A. versicolor*. *Aspergillus* and *Penicillium* grow superficially on painted surfaces.

Is Dust a Biotic Environment That Supports the Survival of *Aspergillus*?

House dust is a complex mixture of inorganic and organic material that supports a diverse population of fungal species (reviewed in [Rintala et al., 2012](#)). Filamentous molds are able to grow and proliferate in dust only if there is enough moisture present, which in turn is dependent on the relative humidity of the indoor environment. Most of the fungal population originates from sources other than the dust itself, these being outdoor air and other outdoor material, such as vegetation or dirt brought into buildings, occupants of the buildings themselves, including pets and fungal growth on moist building materials. Based on numerous culture

and nonculture based studies, *Penicillium*, *Aspergillus*, *Cladosporium* are the most commonly found in dust depending on the dust type, detection method, type of the indoor environment and season, among other factors. Fungal assemblages in different house dust types usually share the same dominant species; however, alterations in the composition are caused by differing sources of microbes for different dust types. For example, mattress or pillow dust is dominated by species originating from the user of the mattress (Woodcock *et al.*, 2006). Further studies have explored the occurrence of fungi in furniture stuffings and upholstery as well as house dust in relation to asthmatic reactions and allergic sensitization (reviewed in Rintala *et al.*, 2012). The house dust components of fungal origin may include intact fungal conidia, spores, and spore clumps, as well as fragments of spores and hyphae. The size and shape of intact fungal spores varies from tiny, round to ovoid 2–5 μm conidia of *Aspergillus* and *Penicillium*, to large, oblong 50 μm conidia of *Alternaria* and *Helminthosporium*. Fungal fragments vary in size from submicrometer (<1 μm) particles to larger hyphal fragments. Fungal species capable of proliferating in house in the absence of moisture include extreme xerophiles: for example, *Eurotium repens*, *Aspergillus penicilloides* and mixed *Penicillium* species (reviewed in Rintala *et al.*, 2012). Of importance in mechanically ventilated indoor environments is that air filters and ventilation ducts are also colonized by fungi (Noris *et al.*, 2011).

Aspergillus Spore Dispersal in Indoor Air

What are the processes that influence the dispersal and selection regimes of molds in the indoor space? First, it is clear that the majority of indoor air fungi are derived from outdoor air. Second, the variation in fungal communities between houses, for example, is large and partly attributable to selection pressures imposed by resident behavior. A third finding is that airborne fungal communities vary among rooms within a building based on room use. Furthermore, it is expected that cleaning and cooking patterns and exposure to the outdoors will have a predictable effect on the composition of the indoor fungal communities and that the air in rooms with water sources (bathrooms and kitchens) would have a higher burden of resident fungi.

Numerous studies have determined the pattern of fungal diversity and composition in indoor air in specific indoor environments in order to identify processes supporting the array of species. A number of surveys have looked at airborne fungal profiles over seasons of the year seasons, both indoors and outdoors, within and between houses. Fungal communities indoors were diverse and strongly determined by dispersal from outdoors, and no fungal species were found as indicators of indoor air. There was a seasonal effect on the fungi found in both indoor and outdoor air, and quantitatively more fungal biomass was detected outdoors than indoors. Interestingly, room and occupant behavior had no detectable effect on the fungi found in indoor air. These surveys confirm previous reports that outdoor air fungi dominate the spectrum of indoor air. A study reported by the author and colleagues demonstrated that there were only marginal differences in the profile of indoor molds in British homes (Vesper *et al.*, 2005). Analysis of 26 mold indicator species revealed that the homes fell into two clusters, tentatively identified as “atypical” and “typical” mold conditions.

Starting from the premise that the indoor mycobiome is thought to comprise of spore dispersal from the outdoor mycobiome and the occupants’ mycobiome combined with selective pressures imposed by the occupants’ behaviors and the building itself Adams *et al.* determined the pattern of fungal diversity and composition in indoor air within 1-month time periods during two seasons in a university housing facility (Adams *et al.*, 2013). Fungal assemblages indoors were diverse and strongly determined by dispersal from outdoors. No fungal taxa were found as indicators of indoor air and indoor environments. There was a seasonal effect on the fungi found in both indoor and outdoor air, and quantitatively more fungal biomass was detected outdoors than indoors. A strong signal of isolation by distance (IBD, differences between populations at opposite ends of a more or less continuous group of populations) existed in both outdoor and indoor airborne fungal assemblages, despite the small geographic scale in which this study was undertaken (approximately 500 m). Moreover, room and occupant behavior had no detectable effect on the fungi found in indoor air. These results show that at the local level, outdoor air fungi dominate the patterning of indoor air. *Aspergillus* spp. were found in 48% of indoor air samples and in 65% of outdoor samples.

Numbers of Inhaled Conidia

Several assumptions have to be made when discussing the inhalation of *Aspergillus* conidia in indoor environments (reviewed in McCluskey, 2020). Firstly, airborne concentrations of *A. fumigatus* are greater outdoors than they are indoors, provided that the building fabric does not support the growth of the fungus and the environmental conditions are not conducive to spores dispersal. Secondly, the typical concentration of viable *A. fumigatus* spores encountered outdoors has been estimated to be <10 CFU/m³. Thirdly, the concentrations of *A. fumigatus* spores may vary significantly indoors based on the characteristics and maintenance of the occupied building, including the level of settled dust. Fourthly, the average person is a healthy individual, breathing comfortably with a tidal volume of 500 ml. Lastly, *A. fumigatus* spores are evenly distributed throughout the air and remain so in the lungs during breathing. Tidal volume is the term used to describe the normal volume of air a person inhales and exhales in a single breath with no forced effort. Therefore, it is being presumed that with each breath, 500 ml of air is entering the lungs. Further, the normal range for breaths per minute in a healthy adult is considered between 12 and 20 respirations per minute. Thus, a healthy person may take 720–1200 respirations per hour or 17,280–28,800 per day. This translates into a healthy person inhaling and out 8.64–14.4 m³ of air per day. With a conservative assumption that the concentration of *A. fumigatus* spores in the air is nine

CFU/m³, a healthy person might inhale up to 78–130 viable *A. fumigatus* spores per 24-h period. Naturally, there are a number of limitations of attempting to calculate such a number. For instance, some of the assumptions made ignore known characteristics of *A. fumigatus* spores, such as the day to day variability, and possibly even the variability between different areas of the same geographic location. Additionally, there is a lack of data to what is considered normal, or even generally safe, airborne viable spore counts. Further, there is evidence to suggest discordance between *A. fumigatus* spore levels and outbreaks of aspergillosis (reviewed in McCluskey, 2020). Finally, while the calculation here suggests a relatively low number of 78–130 viable *A. fumigatus* spores are inhaled per day, others have estimated that this number could be as high as 200 (reviewed in Dagenais and Keller, 2009). Notably though, these estimates are suggested in countries where typical concentrations of airborne *A. fumigatus* are greater than <10 CFU/m³.

In continental temperate climates *A. fumigatus* spore counts in outdoor environments are generally <10 CFU/m³ with little evidence of seasonal variation, for example in northern Europe (Alshareef and Robson, 2014). In other parts of the world, seasonal variation may explain reports suggesting that *A. fumigatus* spore counts are higher in summer months. Some surveys have suggested that higher concentrations of *A. fumigatus* spores are found in winter (reviewed in McCluskey, 2020). Over a two-year period including a 14-month period of renovation work in a Tunisian hospital, *Aspergillus* spp. were isolated in 59.7% of 494 air samples and in 52.8% of 1579 surface samples taken in various patient rooms (Haleem Khan and Mohan Karuppaiyil, 2012). *Aspergillus* section *Nigri* (72.7%) was the most frequent. *Aspergillus* contamination peaked in autumn and winter on surface and in summer and autumn in air samples and was higher during the renovation work period. In Tunisia, *Aspergillus* section *Nigri* and *Flavi*, but not *Fumigati*, are chiefly involved in invasive aspergillosis.

Diversity of Molds in Social Housing

A study in the US used molecular diagnostic tools to evaluate fungal communities on surfaces and in airborne dust in multiple units of a social housing complex (Sylvain *et al.*, 2019). The investigators surveyed 21 flats and characterized the apartments as either a unit with visible mold or no visible mold. They sampled airborne fungi from dust settled over a month-long time period from the outdoors, in units with no visible mold, and units with visible mold. In the units with visible mold the investigators additionally sampled visible fungal colonies from bathrooms, kitchens, bedrooms, and living rooms. They found that fungal biomass in settled dust was greater outdoors compared to indoors, but there was no significant difference of fungal biomass in units with visible mold and no visible mold. Interestingly, they found that fungal diversity was reduced in units with visible mold compared to units with no visible mold and the outdoors. Units with visible mold harbored fungal communities distinct from units with no visible mold and the outdoors. Colonies of fungi collected from units with visible mold were dominated by two allergenic species, *Cladosporium sphaerospermum* and *Cladosporium halotolerans*. *Aspergillus fumigatus* was not found in any of the indoor samples.

Does the Presence of *Aspergillus* in Home Environments Present a Risk Factor for Invasive Aspergillosis?

In contrast to what is known about exposure to *Aspergillus* in hospitals, little is known about the impact of indoor fungal exposure of hematology patients in their home environment. Rocchi and colleagues investigated the mold exposure of hematology patients both at home and at hospital to assess their risk of acquiring invasive aspergillosis (Rocchi *et al.*, 2014). Fungal exposure was assessed by quantifying opportunistic molds at hospital during hospitalization and in homes of 53 hematology patients. Invasive aspergillosis was diagnosed in 13 of 53 patients and invasive fungal infection in one patient. In hospital, no opportunistic species, or low levels of opportunistic species, were found in 98% of weekly samples. Only 2% of hematology intensive care unit samples showed a high level of *Aspergillus fumigatus* spores in corridor air. Five patients with invasive aspergillosis were hospitalized during these periods. Seven of the 53 homes (5/14 homes of patients with invasive aspergillosis or invasive fungal infection and 2/39 homes of patients without invasive aspergillosis) had a percentage of *A. fumigatus* and *A. flavus* to total mold as high as 15%. The study reinforces the dogma that minimizing exposure to *Aspergillus* in hospital is essential, and that continuous surveillance in the patients' home could help to further reduce the risk of acquiring invasive aspergillosis. Also, advice should be given such as avoiding activity in highly contaminated rooms (for example, a cellar, attic, garage), cleaning rooms where there is visible mold, installing air purifiers, investigating areas of dampness, delaying discharge from hospital, or introducing health monitoring before patients return home if a high risk of fungal infection is suspected.

In marked contrast a survey carried out by Schweer and colleagues determined that there was no correlation between domestic ambient-air spore counts and invasive aspergillosis (Schweer *et al.*, 2016). By air sampling the authors found no correlation between airborne *Aspergillus* spores in patients' homes and development of probable or proven invasive aspergillosis. The authors emphasize that attempts to show a correlation between the presence or level of *Aspergillus* spores in both home and hospital environments and the incidence of invasive aspergillosis have failed repetitively in different study set-ups (reviewed in Schweer *et al.*, 2016). Correlation between spore counts and invasive aspergillosis in the domestic setting is generally more difficult to interpret since the precise time spent in the surroundings by a patient is significantly more variable than in the hospital. Further inference is that the infectious inoculum size and exposure time-frame for developing invasive aspergillosis are unknown.

Aspergillus Mycotoxins in Indoor Environments

Mycotoxin-producing *Aspergilli* (*Circumdati*, *Flavi*, and *Nigri*) may cause respiratory disorders. To explore this further Jakšić *et al.* analyzed air and dust samples from flooded indoor environments (Jakšić *et al.*, 2020). Eleven different species were identified based on their calmodulin marker: *A. ochraceus*, *A. ostianus*, *A. pallidofulvus*, *A. sclerotiorum*, and *A. westerdijkiae* (*Circumdati*); *A. flavus* (*Flavi*); and *A. tubingensis*, *A. welwitschiae*, *A. niger*, *A. piperis*, and *A. uvarum* (*Nigri*). *A. flavus* dominated among airborne isolates (25%) while 56% of the dust borne *Aspergilli* were identified as *A. tubingensis* and *A. welwitschiae*. The ability of identified isolates to produce mycotoxins aflatoxin B1 (AFB1), fumonisin B2 (FB2), and ochratoxin A were assessed by LC-MS analysis. All ochratoxin A (OTA)-producing *Circumdati* belonged to *A. westerdijkiae*. In the section, *Flavi* *A. flavus* produced AFB1 while *A. welwitschiae* and *A. niger* (section *Nigri*) produced FB2. The major conclusion from this study was that water damage substrates supported the growth of aflatoxigenic *A. flavus* in indoor environments. However, the causal relationship of exposure to the mycotoxins produced by these *Aspergilli* with adverse health effects is yet to be determined.

Aspergillus and Hospital Environments

This review has focused on domestic indoor environments. However it is deemed useful to summarize where *Aspergillus* is found in hospital and office environments. In addition to those environmental niches discussed above additional reservoirs of *Aspergillus* growth have been identified in ceiling voids, roller-blind casings, fire proofing material, ventilation ducting and dysfunctional air handling units (Gheith *et al.*, 2015). Active growth in these spaces and on these materials will result in spore formation and dispersal. In hospitals *Aspergillus* specifically has been found contaminating such adhesive tapes, arm bands, plaster. Shower heads within which *Aspergillus* forms biofilms are recognized a risk factor for vulnerable patients in hospitals.

Is the Presence of *Aspergillus Fumigatus* in Indoor Environments Reflected in the Mycobiome of the Respiratory Tract?

Colonization of indoor environments by *Aspergillus* may become significant, and eventually result in *Aspergillus*-related lung disease when the microbiological composition of the normal flora in the respiratory tract is disturbed, such as in the case of an underlying disease, an altered immunological status of the host, or a decrease in ciliary activity of the mucous pulmonary epithelium. The underlying diseases that predispose to aspergillosis could thus provide significant insights into which alterations in the respiratory tract microbiome might predispose to aspergillosis. The fungi that reside in the human lungs represent an understudied but medically relevant community. This thesis has been reviewed by Richardson *et al.* (2019). From the few studies about the lung mycobiome, it is clear that there are fungi in both the healthy and diseased respiratory tract, that these fungi vary widely between individuals, and that there is a trend toward lower fungal diversity among individuals with chronic or progressive respiratory disease. Another dimension to the above discussion is the persistence or clearance of fungal conidia and hyphal fragments in healthy or debilitated individuals from the various levels of the respiratory tract. The primary route of human infection is via the inhalation of these airborne conidia, followed by conidial deposition in the bronchioles or alveolar spaces. In healthy individuals, conidia that are not removed by mucociliary clearance encounter epithelial cells or alveolar macrophages, the primary resident phagocytes of the lung. Alveolar macrophages are primarily responsible for the phagocytosis and killing of *Aspergillus* conidia as well as the initiation of a proinflammatory response that recruits neutrophils to the site of infection. Conidia that evade macrophage killing and germinate become the target of infiltrating neutrophils that are able to destroy hyphae. The risk of developing invasive aspergillosis results primarily from a dysfunction in these host defenses in combination with virulence attributes that permit *A. fumigatus* survival and growth in this pulmonary environment. It is patently clear from the surveys reviewed that healthy individuals and patients are exposed to a diverse collection of fungal taxa and species in outdoor and indoor environments. As we have seen, *A. fumigatus* is able to grow and sporulate on a variety of organic substrates in outdoor indoor niches and release conidia into the air. Mycobiome studies of air and dust demonstrate this very clearly. The appearance of *Aspergillus* in indoor locations is most likely as a result of migration of conidia from outside considering that there are few substrates and microenvironments to support the growth of *Aspergillus* in well-maintained homes. The interesting question is whether the lung mycobiome reflects the diversity of fungi in outdoor and indoor environments. Richardson *et al.* suggest that based on their review of the lung mycobiome, that the answer is no (Richardson *et al.*, 2019). *Aspergillus* species are under-represented in many respiratory tract mycobiome analyzes.

Introduction

In agricultural environments it's possible to find fungi in many stages of their development. The presence of these microorganisms poses as a threat to the final quality of the products, to its workers, and most of the times causing significant losses on the annual crops harvest (Korbas, 2004; Weber, 2007; Suchorzyńska and Misiewicz, 2009). Fungi can be easily found in this kind of environments due to the good growth conditions that are provided by the raw materials present in this environment and for its storage temperatures (Soroka *et al.*, 2008).

The fungal variety present in agricultural matrices are influenced by several environmental factors, such as the type of crop and cultivation, the local climate and the application of fertilizers and pesticides (Girsch and Weinhappel, 2004; Szwajkowska-Michalek *et al.*, 2010).

Although the normal presence of fungi in the environment, the exposure is mostly through dust particles released from cereals and other agricultural products during handling and storage operations (Mbareche *et al.*, 2019). This kind of particles represents a real hazard regarding the pathogenesis of respiratory tract diseases in farmers (Nardell and Macher *et al.*, 1999). Fungi are among the particle's components (Jenerowicz *et al.*, 2012), and due to the daily activities, their suspension in the air is frequent, promoting workers's exposure. Particles can be responsible for numerous health problems due to its ability to be airborne, thus classifying itself as a vector for infectious diseases (WHO, 1999; Roy and Milton, 2004; Yu *et al.*, 2004; Li *et al.*, 2007; Eames *et al.*, 2009).

The level of the impact on the workers' health from their exposure to bioaerosols will depend of 4 main factors: Size of the particles, chemical compositions, microbiological composition and its concentration on the environment (Żukiewicz-Sobczak *et al.*, 2012). Indeed, studies report that workers in agriculture environments are exposed to high levels of microbial components (Żukiewicz-Sobczak *et al.*, 2012; Menga *et al.*, 2016), being already reported symptoms related to cough, inflammation of the eyes and nose, asthma and others (Melbostad and Eduard, 2001; Eduard *et al.*, 2004; van der Walt *et al.*, 2010; Chowdary *et al.*, 2011; Schlünssen *et al.*, 2011; Żukiewicz-Sobczak, 2013a). In the specific case of exposure to fungi it was already reported as being related with several symptoms in the eyes and nose and to cough (Melbostad and Eduard, 2001) as well as to asthma and work-related respiratory symptoms (Eduard *et al.*, 2004; Schlünssen *et al.*, 2011).

Although the major concern when exposed to an environment is the fungal contamination, mycotoxins, produced by some fungal species, are also of concern, since can origin chronic and acute effects. Some of these mycotoxins also have carcinogenic and mutagenic characteristics, causing damage in internal organs, lowering the organism natural defences and accelerating the development of tumors (Maestrelli *et al.*, 2009; Frac *et al.*, 2015).

The more frequently reported fungi in agricultural settings are species from the genera *Aspergillus*, *Alternaria*, *Fusarium*, *Penicillium*, and *Cladosporium*. The *Alternaria alternata* is also a quite common species in agricultural environments (Saur *et al.*, 1984; Krysińska-Traczyk *et al.*, 2003; Maestrelli *et al.*, 2009; Żukiewicz-Sobczak *et al.*, 2012; Frac *et al.*, 2015; Kozak *et al.*, 2016).

The climate conditions are one of the most selective factors for the prevalence of species in this kind of environments. Indeed, species of the genera *Fusarium* prefer high levels of persisting humidity and temperatures above 20°C (Brennan *et al.*, 2003, 2005), while *Aspergillus* prefers higher temperatures in between 30°C and 35°C for optimal growth (Kozakiewicz and Smith, 1994; Lasram *et al.*, 2010; Shehu and Bello, 2011).

This systematic review aims to provide a broad overview of the state of art in the developed subject, indicating the most critical scenarios, among agriculture environments has the highest prevalence of fungal species and which methods were applied to assess the exposure to fungi on agricultural environments.

Materials and Methods

This study was done based on a systematic search of available information and data published in the public domain between the period of 1st January 2000 and 31st November 2019.

Baseline search parameters were established to identify and select studies in agricultural environments accessing fungi and mycotoxins. Appropriate search terms were employed to the selected databases (PubMed, B-on, and Web of Science). All the searches on the databases were done in English, the strategy of research mainly focused on agricultural settings, on fungi and mycotoxins, selecting only English and original papers.

The final result of this search strategy resulted in 18 PubMed, B-on, and Web of Science papers, all the articles that did not meet the selected inclusion criteria were excluded ([Table 1](#)). The findings were compared for consistency and discrepancies were highlighted; a final selection of papers was fixed.

The diagram describes the different phases of the selection of papers ([Fig. 1](#)).

Table 1 Inclusion and exclusion criteria in the articles selected

<i>Inclusion Criteria</i>	<i>Exclusion Criteria</i>
Articles published in the English language;	Articles published in other languages
Articles published from 1st January 2000 to 31st November 2019	Articles published prior to 2000
Articles published in any country	
Articles related to fungi assessment in agricultural settings	Articles related exclusively to biologic samples from patients or without mention of fungi quantification.
Original scientific articles on the topic	Abstracts of congress, reports, reviews/state of the art articles

Fig. 1 PRISMA based selection of articles.

Results

A total of 18 articles were analyzed regarding agricultural environments (Crop handling, processing plants, and other agricultural activities), the sampling methods used, the analytical methods, how the fungal identification was performed and the main findings of each of the selected studies.

The majority of the studies analyzed were set on farms (10 out of 18), the others were developed on agricultural processing plants (5 out of 18) and in agricultural handling sites (3 out of 18). Three studies used organic and conventional farms for comparison purposes (Żukiewicz-Sobczak *et al.*, 2012, 2013b,c).

The most frequent sampling method used across all studies was air filtration methods, used in 8 of the 18 studies (Adhikari *et al.*, 2004; Góra *et al.*, 2004; Skórska *et al.*, 2005a,b; Lee *et al.*, 2006; Madsen, 2006; Halstensen *et al.*, 2007; Madsen *et al.*, 2012). The exclusive use of active sampling was the most common approach in the selected studies (10 out of 18 studies) followed by the use of passive methods (5 out of 18), while the combination of the two types of sampling was only stated in 3 studies (Krysińska-Traczyk *et al.*, 2004; Shenoi *et al.*, 2005; Madsen *et al.*, 2012). Among the passive methods used in the studies the most common was the direct sampling of grain or other agricultural products (Reboux *et al.*, 2002; Krysińska-Traczyk *et al.*, 2007; Madsen *et al.*, 2012; Żukiewicz-Sobczak *et al.*, 2012, 2013b) but was also used as passive methods the collection of settle dust (Góra *et al.*, 2004; Krysińska-Traczyk *et al.*, 2007; Żukiewicz-Sobczak *et al.*, 2012) and the collection of soil samples (Shenoi *et al.*, 2005; Żukiewicz-Sobczak *et al.*, 2013b).

Across all studies the only method of fungal identification used was the morphological identification obtained by culture-based methods. *Alternaria alternata* was the most identified species across all studies, found in 9 out of 18 studies (Dutkiewicz *et al.*, 2002; Góra *et al.*, 2004; Krysińska-Traczyk *et al.*, 2004; Skórska *et al.*, 2005a,b; Krysińska-Traczyk *et al.*, 2007; Żukiewicz-Sobczak *et al.*, 2013b,c; Zawiaślak *et al.*, 2019), although the genera more commonly found was the *Aspergillus* genera (15 out of 18 studies) in which species like *Aspergillus fumigatus* (Dutkiewicz *et al.*, 2002; Krysińska-Traczyk *et al.*, 2004; Skórska *et al.*, 2005a,b; Madsen, 2006; Madsen *et al.*, 2012; Zawiaślak *et al.*, 2019), *Aspergillus flavus* (Żukiewicz-Sobczak *et al.*, 2012), *Aspergillus versicolor* (Żukiewicz-Sobczak *et al.*, 2013b), and *Aspergillus ochraceus* (Krysińska-Traczyk *et al.*, 2007) were also found.

Less prevalent than the *Alternaria* and *Aspergillus* genera, was also found *Mucor* sp. (7 out of 18 studies), *Fusarium* sp. (6 out of 18 studies) and *Candida* sp. (4 out of 18 studies) (Table 2).

Discussion

Alternaria, *Aspergillus*, *Mucor*, and *Fusarium* were the most common genera found across all the papers. Among these some genera raise a higher concern than others, such as the *Aspergillus* and *Mucor* genera. It was already reported high prevalence of both genera in indoor and occupational environments (Viegas *et al.*, 2017; Caetano *et al.*, 2019) leading to health hazards and the rise of cases of *Aspergillus* and *Mucor* infections (Kontoyiannis *et al.*, 2005; Bitar *et al.*, 2009; Auberger *et al.*, 2012).

Aspergillus is a very common filamentous fungal genus that can be found in many different environments, usually they are classified as saprophytes, but in some cases, they can also be pathogenic and cause harm to humans (Heitman, 2011; Seyedmousavi *et al.*, 2015). This genus is classified as an opportunistic pathogen that may cause a wide range of respiratory disorders (Hope *et al.*, 2005). The conidia are very persistent in the environment and can stay viable for several months. Additionally they are well suited for airborne dispersion (Pringle *et al.*, 2005). Furthermore, the presence of *Aspergillus* should not be neglected due to some of its sections being able of producing toxic compounds (Varga *et al.*, 2015; Viegas *et al.*, 2018b) and also due to the increasing occurrence of antifungal resistance in clinic and environmental settings (Fairlamb *et al.*, 2016; Nature Microbiology, 2017).

Mucorales order is known to be prevalent in indoor and occupational environments (Caetano *et al.*, 2017, 2018a; Viegas *et al.*, 2018a), and it includes a variety of saprophyte species that may cause serious infections, as the mucormycosis (Caetano *et al.*, 2018b), or other serious health problems (Laverne *et al.*, 2017). As mentioned Mucorales cases are on the rise and the increase of azole resistant strains. Their cross-resistance characteristics show a more critical scenario regarding the therapeutics and management of fungal infections (Leathers and Sypherd, 1985; Cuenca-Estrella, 2014). This problem is perhaps result of the drawback of exposure to antifungal drugs or other related chemicals that may lead to a review of the current therapy for these cases due to potential treatment failures (Nature Microbiology, 2017). Moreover, *Mucor* genera in Europe is one of the most identified fungi (Kwon-Chung, 2012; Lanternier *et al.*, 2012).

The level of exposure to fungi may be increased when present in certain settings where the levels of organic dust generated is high. The particles act as carriers of the microorganisms leading to the dispersion of the fungi being carried (Caetano *et al.*, 2018a; Viegas *et al.*, 2020). Scenarios such as this, where exposure to organic dust is high, may be found in agricultural environments (Nardell and Macher *et al.*, 1999; Jenerowicz *et al.*, 2012; Mbareche *et al.*, 2019).

Among the sampling methods employed in all the studies observed, the exclusive use of active methods were the most common approach (10 out of 18 studies) and with 5 out of 18 studies using exclusively passive methods, while the combined use of both methods were only stated in 3 out of 18 studies. The usage of passive and active sampling has some advantages and disadvantages. The passive methods are considered to be a very versatile technique to detect the microbial contamination in various settings, allowing a better understanding of the contamination present and an improved characterization of indoor environments (Viegas *et al.*, 2014, 2016a; Caetano *et al.*, 2017). Active sampling can provide information about the load in air at

Table 2 Data obtained from the chosen articles

Database	Title	Country	Environment description	Sampling methods	Analytical Methods	Results	Main findings	References
PubMed	Exposure to airborne microorganisms, dust and endotoxin during flax scutching on farms	Poland	Five flax farms	Custom particle-sizing slit impaction sampler	Morphological identification	<i>Alternaria alternata</i> , <i>Aspergillus fumigatus</i> , <i>Candida</i> spp. <i>Fusarium</i> spp. <i>Mucor</i> spp. <i>Penicillium</i> spp.	Flax scutching represent high exposure concentrations to airborne organisms, adding to this the presence of allergenic and immunotoxic species were stated. 	Exposure of hop growers to bioaerosols	Poland	Nineteen Hop farms	Air filtration, settle dust collection	Morphological identification	<i>Alternaria alternata</i> , <i>Alternaria humicola</i> , <i>Aspergillus candidus</i> , <i>Cladosporium elegantum</i> , <i>Cladosporium epiphyllum</i> , <i>Mucor mucedo</i> , <i>Mucor Racmosus</i> , <i>Penicillium citrinum</i> , <i>Penicillium</i> spp. <i>Trichoderma viride</i>	The exposure levels of hop growers are much lower than in other crops, although allergen species present still represent a potential hazard.	Góra <i>et al.</i> (2004)
	Exposure to Airborne Microorganisms, Dust and Endotoxin During Processing of Peppermint and Chamomile Herbs on Farms	Poland	Thirteen Herb Farms (peppermint and chamomile)	Personal and stationary air filtration	Morphological identification	<i>Alternaria alternata</i> , <i>Aspergillus fumigatus</i> , <i>Candida</i> spp. <i>Cladosporium cladosporioides</i> , <i>Cladosporium herbarum</i> , <i>Fusarium</i> spp. <i>Geotrichum cardinum</i> , <i>Oidiodendron</i> spp. <i>Penicillium</i> spp. <i>Rhodotorula rubra</i>	These farmers are exposed to large concentration of airborne microorganisms. At 50% of the sites sampled fungi were the dominant airborne microorganisms, where allergenic species were commonly found.	Skórska <i>et al.</i> (2005a)
	Size-selective assessment of agricultural workers' personal exposure to airborne fungi and fungal fragments	Taiwan	One corn farm and one mushroom farm	Personal Cyclone air sampler (impinger)	Morphological identification	<i>Aspergillus</i> spp. <i>Penicillium</i> spp. <i>Alternaria</i> spp. <i>Botrytis</i> spp. <i>Cercospora</i> spp. <i>Cladosporium</i> spp.	<i>Aspergillus</i> , <i>Penicillium</i> and <i>Cladosporium</i> represented 15%–99% of fungal concentration. <i>Alternaria</i> and <i>Botrytis</i> produces small metabolites (< 1 µm) representing risk to human health.	Lee <i>et al.</i> (2011)
	Rye grains and the soil derived from under the organic and conventional rye crops as a potential source of biological agents causing respiratory diseases in farmers	Poland	Two organic farms and two conventional farms	Collection of rye grain and soil samples	Morphological identification	Organic Farms: <i>Alternaria alternata</i> , <i>Aureobasidium pullulans</i> , <i>Paecilomyces variotii</i> , <i>Penicillium citreo-viride</i> , <i>Penicillium glabrum</i> , <i>Penicillium lilacinum</i> Conventional farms: <i>Alternaria alternata</i> , <i>Aureobasidium pullulans</i> , <i>Cladosporium herbarium</i> , <i>Cladosporium oxysporum</i> , <i>Aspergillus versicolor</i> , <i>Penicillium citreo-viride</i> , <i>Penicillium funiculosum</i> , <i>Penicillium glabrum</i> , <i>Penicillium lilacinum</i>	Significant exposure was verified due to hazardous agents present in grain and soil. Allergenic and toxigenic molds were also found.	Żukiewicz-Sobczak <i>et al.</i> (2013b)
Web of Science	Exposure to airborne microorganisms and endotoxins in a potato processing plant	Poland	Potato processing plant	Custom particle-sizing slit impaction sampler	Morphological identification	<i>Alternaria alternata</i> , <i>Aspergillus fumigatus</i> , <i>Aspergillus niger</i> , <i>Candida</i> spp. <i>Geotrichum candidum</i> , <i>Mucor</i> spp. <i>Rhizopus nigricans</i>	Potato processing plants represent high exposure concentrations to airborne microorganisms, mainly when handling dried potatoes.	Dutkiewicz <i>et al.</i> (2002)

(Continued)

Table 2 Continued

Database	Title	Country	Environment description	Sampling methods	Analytical Methods	Results	Main findings	References
	Assessment of human exposure to airborne fungi in agricultural confinements: Personal inhalable sampling Versus Stationary sampling	USA	Grain handling site	Personal and stationary air filtration	Morphological identification	Stationary Samplers: <i>Aspergillus</i> spp. <i>Penicillium</i> spp. <i>Cladosporium</i> spp. <i>Alternaria</i> spp. Personal Samplers: <i>Aspergillus</i> spp. <i>Penicillium</i> spp. <i>Cladosporium</i> spp. <i>Alternaria</i> spp.	Potential hazardous fungi were found, but low variety of flora were verified. The results in the two methods were almost similar revealing that the sensitivity of button sampling is low in confined environments.	Adhikari et al. (2004)
	Exposure to Airborne Microorganisms, Dust and Endotoxin during Processing of Valerian Roots on Farms	Poland	Fifteen Herb farms (valerian root)	Personal and stationary air filtration	Morphological identification	<i>Alternaria alternata</i> , <i>Aspergillus candidus</i> , <i>Aspergillus fumigatus</i> , <i>Aspergillus glaucus</i> , <i>Aspergillus niger</i> , <i>Aspergillus terreus</i> , <i>Candida</i> spp. <i>Cylindrocarpum</i> spp., <i>Fusarium</i> spp. <i>Humicola</i> spp., <i>Monilia</i> spp. <i>Mucor mucedo</i> , <i>Mucor</i> spp. <i>Oidiodendron flavum</i> , <i>Penicillium</i> spp. <i>Rhizopus nigricans</i> , <i>Rhodotorula rubra</i> , <i>Trichoderma album</i> , <i>Trichothecium roseum</i>	Only after the drying of roots is verified the prevalence of <i>Aspergillus fumigatus</i> , this being one of the main hazards found due to the health risks posed to the respiratory tract.	Skórska et al. (2005b)
	Exposure to airborne microbial components in autumn and spring during work at Danish biofuel plants	Denmark	Five biofuel plants	Personal air filtration	Morphological identification	Total fungi (range from $1.1-130 \times 10^4$ cfu/m ³) Mesophilic fungi (range from $0.043-20 \times 10^4$ cfu/m ³) <i>Aspergillus fumigatus</i> (range from $0-2.48 \times 10^4$ cfu/m ³)	High exposure capable of causing health disorders were found. <i>A. fumigatus</i> were most found in wood chips.	Madsen (2006)
	Levels of fungi and mycotoxins in the samples of grain and grain dust collected from five various cereal crops in Eastern Poland	Poland	Twenty-four private farms	Collection of grain and grain dust samples	Morphological identification	<i>Alternaria alternata</i> , <i>Aspergillus ochraceus</i> , <i>Aspergillus niger</i> , <i>Cladosporium elegantulum</i> , <i>Cladosporium herbarum</i> , <i>Cladosporium lignicola</i> , <i>Geotrichum candidum</i> , <i>Monilia sitophila</i> , <i>Monosporium silvaticum</i> , <i>Mucor mucedo</i> , <i>Oidiodendron griseum</i> , <i>Oidiodendron fl avum</i> , <i>Penicillium</i> spp. <i>Prophytroma tubularis</i> , <i>Rhizopus artocarp</i> , <i>Rhizopus nigricans</i> , <i>Rhodotorula rubra</i> , <i>Trichoderma Album</i>	Although the concentrations found were low, the prevalence of these fungi were almost constant (90%), leading to high bioavailability of mycotoxins through inhalation, causing possible chronic effects.	Krysińska-Traczyk et al. (2007)
	Determinants of microbial exposure in grain farming	Norway	Eleven grain farms	Personal and stationary air filtration	Morphological identification	Fungal spores (10^6 /m ³) range:5200 Actinomycetes (10^6 /m ³) range:3000 Hyphae (10^6 AU/m ³) range:200	Despite farmers practices to prevent fungal growth, were verified high exposure levels. Visible fungal damage were the main determinants of exposure to inhalable dust and its microbial components.	Halstensen et al. (2007)

B-On	Organic dust toxic syndrome at a grass seed plant caused by exposure to high concentrations of bioaerosols	Denmark	Grass seed plant	Collection of grass seed samples, personal air filtration	Morphological identification	Mesophilic fungi (range from 6.9×10^5 – 7.95×10^6 cfu/m ³) <i>Aspergillus fumigatus</i> (range from 3.20×10^5 – 6.79×10^6 cfu/m ³)	It was found <i>A. fumigatus</i> to be released in very high quantities from the problematic seeds. All direct handling of the problematic seeds seemed to imply a serious exposure even after cleaning. Concentrations found in ecological farms were lower.	Madsen et al. (2012)
	Pathogenic fungi in the work environment of organic and conventional farms	Poland	Organic and conventional farms	Collection of wheat and wheat dust samples	Morphological identification	Organic Farms: <i>Aspergillus flavus</i> , <i>Cladosporium</i> spp. <i>Cladosporium macrocarpum</i> , <i>Fusarium</i> spp. Conventional Farms: <i>Cladosporium</i> spp. <i>Fusarium</i> spp., <i>Gonatotryps</i> spp. <i>Ulocladium</i> spp.	The isolates show a direct relation between metabolites and health effects reported in farmers.	Żukiewicz-Sobczak et al. (2012)
	Influence of buffered propionic acid on the development of micro-organisms in hay	France	Seventeen hay farms	Probe sampling of hay	Morphological identification	<i>Eurotium amstelodami</i> , <i>Alternaria</i> spp. <i>Mucorales</i> spp.	The use of BPA reduced greatly (40%–65%) the prevalence of fungal species present in hay.	Reboux et al. (2002)
	Dermatoses among paddy field workers – A descriptive, cross-sectional pilot study	India	Paddy field workers	Air and water sampling (culture collection), soil sampling	Morphological identification	<i>Aspergillus</i> spp. <i>Penicillium</i> spp. <i>Fusarium</i> spp. <i>Curvularia</i> spp. <i>Mucor</i> spp. <i>Synphelastrium</i> spp.	Working in paddy fields leads can traumatize the skin leading to lacerations, were microorganisms present in the grains can cause dermatitis.	Shenoi et al. (2005)
	Personal exposure to airborne dust and microorganisms in agricultural environments	USA	Three grain farms	Personal air filtration	Morphological identification	<i>Aspergillus</i> spp. <i>Penicillium</i> spp. <i>Cladosporium</i> spp. <i>Alternaria</i> spp. <i>Epicoccum</i> spp.	The exposure in the farms were mainly due to large particles with high fraction of fungal spores.	Lee et al. (2006)
	Grain dust originating from organic and conventional farming as a potential source of biological agents causing respiratory diseases in farmers	Poland	Organic and conventional farms	Settle dust collection	Morphological identification	Organic Farms: <i>Alternaria alternata</i> , <i>Aureobasidium pullulans</i> , <i>Cladosporium macrocarpum</i> , <i>Fusarium poae</i> , <i>Fusarium oxysporum</i> Conventional Farms: <i>Alternaria alternata</i> , <i>Cladosporium macrocarpum</i> , <i>Fusarium poae</i> , <i>Fusarium tricinctum</i>	Components of grain dust show potential risks containing toxigenic and allergenic molds. Most of Polish occupational diseases reported by farmers are caused by pathogens in bioaerosols.	Żukiewicz-Sobczak et al. (2013c)
	Microbiological analysis and concentration of organic dust in an herb processing plant	Poland	Herb processing plant	Impaction air sampler	Morphological identification	<i>Aspergillus fumigatus</i> , <i>Penicillium citrinum</i> , <i>Alternaria alternata</i>	The type of raw material processed at a processing line is an important factor. <i>A. fumigatus</i> and <i>P. citrinum</i> constituted the dominant flora.	Zawiaślak et al. (2019)

the moment of sampling, since it only collects a portion of the air of the sampled site (Napoli *et al.*, 2012). Thus, the application of active methods coupled with passive methods is recommended, as this way it is possible to obtain more reliable data from long-term periods (Viegas *et al.*, 2017; Leppänen *et al.*, 2018). The integration of different kinds of methods allows the collection of a more refined and useful data without having to rely in a single method to represent a given scenario (Viegas *et al.*, 2017; Leppänen *et al.*, 2018).

Across all the studies that were analyzed it was stated a single analytical approach: morphological identification based on culture-based methods. This method it is considered a well-known and validated method for microbiological studies allowing to assess living and culturable microorganisms. It is easily recognizable and quantifiable the viable cells in a sample and has a high sensitivity when paired with the appropriate media (Figdor and Gulabivala, 2011). However, it has several drawbacks, such as the risk of external contamination, its time and resource intensive, it requires a certain level of skill to achieve optimal results and relies on the phenotypic biochemical characterization that may lead to favoring only some of the viable microorganisms (Jannasch and Jones, 1959; Amann *et al.*, 1995; Schmit and Lodge, 2005; Liu, 2011; Alsohaili and Bani-Hassan, 2018; Viegas *et al.*, 2019). The underestimation is the major limitation of this method, since can dramatically underestimate the numbers and composition in the samples (Figdor and Gulabivala, 2011; Al-Awadhi *et al.*, 2013). Molecular tools can overcome some of the limitations, since provides a faster and more accurate description of the microbial communities present in each sample, compared to the culture-based methods (Alsohaili and Bani-Hassan, 2018). However, as the culture based-methods, molecular tools have also some restrains related to the preferential sequencing of some species, the use of inadequate primers or the result being the production of single bands (Polz and Cavanaugh, 1998; Sipos *et al.*, 2007). Thus, it is advised to use in parallel both methods. Indeed, it was reported that the single use of culture-based methods or molecular tools may lead to entirely different results (Al-Awadhi *et al.*, 2013), adding up the importance to apply both.

Conclusions

This study raises concern to occupational exposure to fungi on agriculture environments due to high concentrations of organic dust present and highlights the importance to use more than one sampling and assay methods to have an accurate exposure assessment.

Fungal Contamination of Beaches

Esther Segal, Tel Aviv University, Tel-Aviv, Israel

Introduction

Mentioning beaches will evoke in most of us an image of golden sands, palm trees and an exotic cocktail in a coconut. Zooming in on the sand and water the picture is much less idyllic. A myriad of microorganisms, including viruses, bacteria, fungi, and protozoa, thrive in these ecosystems in complex patterns. Since beaches have an enormous potential for revenue, linking them to human infectious diseases outbreaks, could have significant economic repercussions (Sabino *et al.*, 2014a). Thus, the study of various aspects of potential pathogens and ways to minimize the risk of their involvement in human disease is of importance.

Although less studied than bacterial contaminants, mostly linked to fecal contamination, this review will focus on potential fungal pathogens. It will summarize the major findings as represented in scientific literature regarding the fungal contamination of sand and water on beaches, primarily in context of association to human health and wellbeing. It will not cover, specifically, the data of original research of the authors in this area, but rather mention it briefly.

Surveyed Beaches

Surveys of salt and sweet water beaches for potential pathogens were conducted in many countries and regions. Many of these surveys dealt only with fecal contamination indicator (FCI) bacteria.

Surveys on fungal contamination were carried out in various geographic areas, including a variety of water bodies. Surveys on beaches around the Pacific Ocean were reported from Hawaii (Kishimoto and Baker, 1969), California (Dabrowa *et al.*, 1964), Guadeloupe (Boiron *et al.*, 1983), Brazil (Gomes *et al.*, 2008; Vieira *et al.*, 2001; Menezes and Trindade, 1996, cited from Vieira *et al.*, 2001; Sanchez *et al.*, 1986; de Moura Sarquis and de Oliveira, 1996; Pinto *et al.*, 1992; Sato *et al.*, 2005; Zuza-Alves *et al.*, 2019), and Barbados Bridgetown, Puerto Rico and St. Maarten (Lourdes, 2019).

The second large saltwater body – the Atlantic Ocean was also surveyed, including beaches in Florida (Bergen and Wagner-Merner, 1977; Vogel *et al.*, 2007; Shah *et al.*, 2011), South Carolina (Stevens *et al.*, 2012), and Portugal (Romão *et al.*, 2017; Sabino *et al.*, 2011; Sabino *et al.*, 2014b, Abreu *et al.*, 2016; Pereira *et al.*, 2013; Mendes *et al.*, 1998; Brito *et al.*, 2019).

The Mediterranean is another saltwater body around which surveys were conducted. These included the coasts of Israel (Sheinman *et al.*, 2000; Ghinsberg *et al.*, 1994; Frenkel *et al.*, 2020), Morocco (Soussi Abdallaoui *et al.*, 2007), Spain (Borrego *et al.*, 1991; Izquiere, Piera, Aledany and Lucena, 1986, cited from Matavulj *et al.*, 2005; Roses Codinachs *et al.*, 1988; Larrondo and Calvo, 1989), Greece (Efstratiou and Velegraki, 2010; Papadakis *et al.*, 1997), Egypt (Sharaf, 2005), Italy (Mancini *et al.*, 2005), and France (Bernard *et al.*, 1988, cited from Matavulj *et al.*, 2005).

The Israeli beaches around the very high salt concentration water body – the Dead Sea – were surveyed as well (Buchalo *et al.*, 1998).

Results of surveys conducted on beaches of freshwater bodies were reported from Canada (Sherry *et al.*, 1979) and France (Chabasse *et al.*, 1986).

The Fungal Flora in Beaches

Unsurprisingly, considering the extreme variations in the conditions of the different beaches screened, the variety of isolated fungi comprises hundreds of genera and species. Three species of extreme halophile fungi were found even in the Dead Sea (Buchalo *et al.*, 1998). Moreover, the application of non-cultural screening methods has further incremented the gamut of fungal varieties found on beaches (Romão *et al.*, 2017).

Potentially pathogenic or allergenic fungi are often found on beaches. The most common are *Aspergillus* spp., *Penicillium* spp., *Fusarium* spp., and the *Mucorales* (Matavulj *et al.*, 2005; Mancini *et al.*, 2005; Sabino *et al.*, 2014b). To the best of our knowledge, the question whether these environmental fungi are more frequent on the beaches than in other ecosystems has not been addressed. Other, potentially pathogenic, fungi isolated from beaches include *Scedosporium apiospermum* and *Sporothrix schenckii* (Dabrowa *et al.*, 1964).

An important group of fungi that infect immunocompetent humans and animals are the dermatophytes. These fungi may be shed in the environment by hair or scales of infected humans and animals. It has been suggested (Szepietuk *et al.*, 2010) that the abrasive action of the sand, especially if wet, may promote the shedding of these scales and thus increase the risk of infecting new hosts. In fact, Soussi Abdallaoui *et al.* (2007) isolated dermatophytes exclusively from wet sand. This is further facilitated by the skin's maceration due to its exposure to sea water and/or sand moisture.

Paradoxically, dermatophytes were isolated relatively rarely from beaches (Kishimoto and Baker, 1969; Sousa, 1990; Abreu *et al.*, 2016; Szepeitiuk *et al.*, 2010; Pereira *et al.*, 2013; Soussi Abdallaoui *et al.*, 2007; Sabino *et al.*, 2011; Larrondo and Calvo, 1989). It was postulated (Pereira *et al.*, 2013) that their survival under the conditions present on beaches is limited, which would explain the relatively rare person to person transmission (Mancini *et al.*, 2005). In fact, several authors noted that their prevalence is related to the influx of bathers to the beaches (Abreu *et al.*, 2016; Szepeitiuk *et al.*, 2010). Sabino *et al.* (2011) found the presence of dermatophytes correlated with FCI organisms. Among the dermatophytes found most frequently were *Trichophyton rubrum* and those belonging to the *T. mentagrophytes* complex, probably of human origin and *Microporum canis*, most likely from animals. It is of interest to add that a recent study of the authors (unpublished data) in several beaches of the Mediterranean Israeli coast, did not detect dermatophytes in sand.

Among yeasts, *Candida* species are the most prevalent, especially *C. albicans*, *C. glabrata*, *C. parapsilosis*, and *C. guilliermondii* (Sheinman *et al.*, 2000). Other frequently isolated yeasts belong to the *Rhodotorula* genus. Yeasts, especially *Rhodotorula* spp., were more abundant in the sand than in the water (Shah *et al.*, 2011). It is noteworthy that *C. albicans* and *Rhodotorula* spp. may be carried in the human gastrointestinal tract and thus their isolation may be an indicator of fecal contamination. In fact, several authors (Borrego *et al.*, 1991; Sabino *et al.*, 2011; Sherry *et al.*, 1979) found a correlation between the presence of these yeasts and bacterial fecal contamination indicators such as *Escherichia coli*, enterococci or *Clostridium perfringens* (Shah *et al.*, 2011). Zuza-Alves *et al.* (2019) found *C. tropicalis* isolates from one beach to be heterogeneous, relatively stable during one season and dispersed over long tracts of the beach, possibly through anthropogenic activities. More rarely, *Cryptococcus neoformans*, possibly from bird droppings was isolated (Kishimoto and Baker, 1969). Another *Cryptococcus* species, *Cr. uzbekistanensis*, with potential ability to infect humans (Powel *et al.*, 2012) was found in sand (Segal, unpublished data).

The Ecosystem

The seashore is an extremely variable environment (for a review see Whitman *et al.*, 2014). The exposure of the sand to water is an important source of this variability: it may be submerged (infra-tidal zone), bathed by the waves (swash zone), by the tides (inter-tidal zone) or dry (supra-tidal zone). Moreover, sea spray, influenced by wind, may have an impact on the sand's moisture.

Climatic variations such as intensity and duration of exposure to sun radiation, wind causing movement of the sand, rain, and temperature may influence the beach microbiome.

The chemical composition of the sand and its physical characteristics may influence the quantity, composition, and tendency to form biofilms of the microbiome. Parameters of significance are the content in organic material, acidity, and salinity. Grain size may influence the impact of winds on the diffusion of point contaminations and the channels in the sand through which microorganisms can diffuse.

The composition of the microbiome may vary in time due to differences in the multiplication ability of the various microorganisms and the synergistic or antagonistic interaction between them.

Sources of microbial contamination may be anthropogenic activities originating from the extent of people frequenting the area, effluents running through it or contamination of nearshore seawater. An additional factor to be considered are animal excrements such as bird droppings or pet feces.

All these variables and their interaction have a significant impact on the composition of the microflora in general and the mycoflora in particular. Their study is important for geographical comparisons, as indicators of contamination and the possible presence of pathogenic fungi.

Sand seems to be a more suitable environment as yeasts are more abundant in it than in water. Moreover, dry sand seems to be more richly populated by yeasts than wet sand (Vieira *et al.*, 2001; Papadakis *et al.*, 1997; Sato *et al.*, 2005). This may be due to sand filtering and amassing yeast cells brought in by high tides and providing a nutrient rich, protected environment (i.e., crannies) (Vogel *et al.*, 2007; Ghinsberg *et al.*, 1994; Mancini *et al.*, 2005). Interestingly, FCI bacteria seem to prefer the moist areas (Whitman *et al.*, 2014). Moreover, the adsorbing surface of the sand grains, their mineral composition and oxygenation may influence the extent of fungal contamination of the sand (Stevens *et al.*, 2012). Abreu *et al.* (2016), found, however, no impact of sand grain size on the level of microbial contamination. *In-vitro* experiments showed that dry-wet cycles and higher temperatures had a negative impact on the survival of some, but not all, fungi associated with beaches. Salinity had no influence on fungal survival in these experiments (Anderson, 1979).

Several authors (De Moura Sarquis and De Oliveira, 1996; Mendes *et al.*, 1998; Chabasse *et al.*, 1986) found seasonality of fungal beach contamination that varied with the fungal species involved. Abreu *et al.* (2016) found no such phenomenon.

Human and Animal Impact on Beach Contamination

Anthropogenic activities may influence the littoral mycoflora. Such is the case for fungi belonging to the *Scedosporium/Pseudallescheria/Lomentospora* complex, often associated with sewers (Al-Yasiri *et al.*, 2017; Alm *et al.*, 2018).

While examining several beaches, Abreu *et al.* (2016) found a heavier burden of fungal contamination on artificial beaches. They attributed this finding to the disruptions of natural water currents and a higher popularity.

Interestingly, pollution seems to cause a decrease of potentially pathogenic microorganisms (Gomes *et al.*, 2008). The interaction between microorganisms may induce self-purification (Chabasse *et al.*, 1986). Such interaction between *Streptomyces* spp. and *Aspergillus* spp., isolated from a Queensland (Australia) beach, were demonstrated in-vitro by Khalil *et al.* (2019).

Beaches may be contaminated by animals that are frequenting it. Gulls and other sea bird droppings are a potential source for such important pathogens as *Cryptococcus neoformans* (Kishimoto and Baker, 1969). In case these birds feed on landfills they may act as vectors transferring microorganisms to the beaches they frequent (Al-Yasiri *et al.*, 2017).

The Relevance of Beach Contamination on Human Health

Human exposure to microorganisms that contaminate beaches and adjacent water may be by ingestion, inhalation and cutaneous exposure causing, respectively, gastrointestinal, respiratory/allergic and skin reactions. Recreational activities in these areas increase the risk due to swallowing of sand and sea waste, especially in children (Abreu *et al.*, 2016), exposing large skin areas for prolonged periods to the sand (i.e., getting buried in it) and inhalation resulting from the heads' relative proximity of the sand (DeFlorio-Barker *et al.*, 2018).

The most widespread and consequently most studied and monitored danger to public health stems from fecal contamination. Among these studies, those focusing on bacterial fecal contamination indicators such as coliforms, enterococci and clostridia are the large majority, whereas fungal microorganisms have received significantly less attention. It was repeatedly noted that levels of fungal contamination of beaches coincided with areas and periods of more intensive human presence (Kishimoto and Baker, 1969; Sherry *et al.*, 1979; Bergen and Wagner-Merner, 1977; Gomes *et al.*, 2008; Vogel *et al.*, 2007; Papadakis *et al.*, 1997). Stevens *et al.* (2012) found, however, that there was no accumulative effect between bathing seasons and non-bathing seasons.

The extent to which beach fungal contamination can be connected to human disease has been rarely assessed (Sabino *et al.*, 2014a), possibly due to the difficulty of gathering adequate data. Among surveys dealing with this topic only a minority includes fungi. In a review, Prüss (1998) noted that there is a dose related association between FCI bacteria and exposure to contaminated recreational waters. Fungal contamination was not included in the review. Heaney *et al.* (2009) and Heaney *et al.* (2012) found that gastrointestinal symptoms but not non-enteric illness was associated with digging in sand and/or getting buried in it and were related to levels of FCI in the sand. (for a more detailed review of bacterial beach contaminants and human disease see Whitman *et al.* (2014)). Although not specifically examined, other authors (Borrego *et al.*, 1991; Sabino *et al.*, 2011; Sherry *et al.* (1979)) have found that yeasts of the genera *Candida* and *Rhodotorula* are associated with such contamination, as well. Fleisher *et al.* (2010) found that a significantly higher risk exists for bathing beach-frequenters to develop gastrointestinal symptoms, acute febrile respiratory illness and skin illness relative to non-bathers. The latter was correlated to levels of contamination with enterococci, the only microorganism tested. No such connection was found for gastrointestinal or respiratory symptoms, caused by other microbial agents. Arnold *et al.* (2013) found that bathers had a higher risk of enteric symptoms, ear inflammation or rash but could not correlate these findings with levels of FCI bacteria. Marino *et al.* (1995) found skin infections to be associated with FCI microorganisms, including *C. albicans* but not dermatophytes. On the other hand, other authors (Chabasse *et al.*, 1986; Colford *et al.*, 2007) found no association between FCI and health risk. Thus, there is currently no unequivocal evidence that FCI microbial counts can be predictive of public health risks for beachgoers (Whitman *et al.*, 2014). The latter observation has undergone currently a revision and restrictive measures are undertaken or proposed by current guidelines for beach contamination (note next section), at this stage only for bacteria, with perspective to add such measures also for fungi.

The gamut of studies on microbial contamination of beaches has been greatly expanded in the last decades due to the states of immunosuppression becoming more common, due to pathological conditions or of iatrogenic origin. Unfortunately, some of the more susceptible populations, such as children are a major component of the populations exposed to these fungi. Increased awareness to these risks has generated a vast number of scientific publications dealing with this topic, which is based on the advancement of methodology, such as metagenomics and chromatography.

Guidelines/Recommendations

Several guidelines and recommendations focused on sampling and criteria for safe use of beaches have been published, such as the United Nations Environment Programme and the World Health Organization documents (for a review see Kamizoulis and Saliba, 2004). For a partial list of relevant websites see Sabino *et al.* (2014a) recommended screening beach sand for human pathogens regularly and the adoption of universal sampling and analysis methods to make inter-laboratory comparison of results meaningful.

Considering the extreme variability of the conditions that may influence the quantity and quality of microorganisms on the beach, repeatability of results may be extremely difficult. Moreover, the timespan during which the results have repercussions on the safety of the beaches for human use is relatively short due to the relatively fast temporal changes in some of these conditions and the possibility of different survival time and reproduction rate of the various microorganisms (Sabino *et al.*, 2011). This complicates attempts to associate human pathology with a specific beach microbial profile since both must be tested in parallel.

Summary

- (1) This chapter summarized the literature on fungal contamination of beaches over the globe.
- (2) The chapter is based on literature reports from different geographic, climatic and demographic sites.
- (3) It included both salt and sweet water bodies.
- (4) The surveyed literature revealed a great variety of fungal species, both yeasts and molds, which could be found in sand and/or in water.
- (5) A number of studies indicated possible associations between fungal contamination and deleterious effects on human health and well-being
- (6) In view of lack of regulatory measures regarding fungal contamination of beaches, the collection of data on the subject, might possibly serve as a database for initiation of regulations for public health.

Fungi and Recreational Water Environments

Recreational water environments are often where we wear less protective clothing against environmental factors, like when we are at the beach. Possible activities that can foster exposure to fungi in recreational waters' sites and settings include the following:

- (1) Bathing in recreational and medicinal waters (public swimming pools, beaches, saunas, spas, etc.)
- (2) Sunbathing
- (3) Water sports (rowboat, kayaking, surfing, fishing, diving, etc.)

Exposure

Swimming Pools

Fungal infection can be a substantial health concern at public swimming pools, due to the prevalence of fungi on hard surfaces, mainly those partly submerged in water, as published by [Ekowati et al. \(2018\)](#). This author postulated that dermatophytes tend to follow the trajectory of the users, from the pool, to the dressing and shower areas, aided by cleaning instruments. These types of fungal contamination are present mainly on solid surfaces in swimming-pool environments. The recognition of public swimming pools as a high risk for *tinea pedis* and onychomycosis is not a new subject. The first time dermatophytes were successfully isolated from shower floors was in 1947 but they still remain an issue today. This is not surprising, though, if we consider that worldwide, 25% of the population suffers from a superficial fungal infection of some kind. Besides the fungi listed above, the yeasts *Candida* and *Rhodotorula* are frequently encountered in water in swimming pools ([Brandi et al., 2007](#); [Jankowski et al., 2017](#)).

Water-borne fungi often thrive in recreational facilities, such as pools and especially high humidity saunas. These can include black yeasts and yeast-like *Aureobasidium*, *Cladophialophora*, *Cyphellophora*, *Exophiala*, *Phialophora*, *Phoma*, and *Ochroconis* ([Matos et al., 2002](#); [Hamada and Abe, 2009](#); [Novak Babič et al., 2018](#)). The damp, warm environment and necessary nutrients for the growth of black fungi make them a probable nuisance for facility management, but above all a potential problem for the health of the visitors and users. Some of the black fungi are considered opportunistic pathogens, causing superficial infections and in some cases of trauma, invasive infections, mainly in form of mycetoma, but occasionally as a disseminated (systemic) infection. Although the most commonly reported health issues related to leisure activities in swimming facilities are on average caused by dermatophytes, other fungi present in high concentrations may affect well-being by triggering an allergic response in susceptible individuals. [Simon-Nobbe et al. \(2008\)](#) describe *Alternaria*, *Aspergillus*, *Bipolaris*, *Cladosporium*, *Curvularia*, and *Penicillium* as triggers of rhinitis; *Alternaria*, *Aspergillus*, *Cladosporium*, *Helminthosporium*, *Epicoccum*, *Aureobasidium*, and *Penicillium* as triggers of allergic asthma; and *Malassezia*, *Schareomyces cerevisiae*, *Alternaria*, *Candida*, and *Trichophyton* as triggers of atopic dermatitis.

Other health implications, such as intoxication due to mycotoxins, sinusitis, asthma, and infections of the respiratory tract, are not likely to occur in occasional visitors but should be taken into consideration for workers in such facilities. Amongst the most problematic molds on wet concrete and finishing materials on ceilings indoors is the presence of *Stachybotrys* spp. Prolonged exposure to toxic metabolites by these fungi can lead to respiratory infections, irritation, and allergies ([Novak Babič et al., 2018](#)). Fungal presence in water and on surfaces is nonetheless difficult to control due to fungal resistance to most agents that can be used for their removal, namely bleach and UV radiation ([DEFRA, 2011](#); [Novak Babič et al., 2018](#)).

While dermatophytes, yeasts and yeast-like fungi dominate lower parts of wet surfaces where exposure happens through skin, upper ceilings often promote growth of filamentous fungi transferred by air with possible effects on our respiratory system. [Viegas et al. \(2011\)](#) found no association between air and surface contaminants, either in quality (species), or quantity (number of colony-forming units (CFU) per sample volume or area, respectively). In this study, the majority of the air contaminants in 200 L of air samples were *Cladosporia* (36.6%), *Penicillia* (19.0%), and *Aspergilli* (10.2%), whereas in surfaces, *Fusaria* showed the strongest presence, with 19.1% of positive samples. *Fusaria* is in fact a species complex that tends to prefer warmer but not dry climates, soil, and plants, as reported by many authors, but also shows up in aquatic habitats ([Lamprecht et al., 2011](#)). Dominant species of this genus may vary between fresh water and seawater ([Palmero et al., 2009](#)). The relevance in aquatic habitats of *Fusarium* species is their association with keratitis in patients with lesions after exposure to water. Contact lenses are also a risk factor for this pathology ([Ahearn et al., 2008](#)). *Fusarium* is, however, not the only fungus able to cause keratitis. [Khater et al. \(2014\)](#) studied 66,303 cases of microbial keratitis and determined that 43.3% of the cases were of fungal origin (mostly *Aspergillus*), although in this study, the patients were mainly adults aged between 40 and 60 years, who had close contact with soil and outdoor sewage.

Sunbathing

Sunbathing is an activity that does not necessarily imply direct contact with recreational waters. By the coast, inevitably, people tend to get their daily dose of vitamin D production and energy at the beach. Considering that most beaches at the coast are composed of sand, which is where recreational beach users tend to spend most of their visiting time, one must wonder why has the regulatory community only worried about water as a potential source of disease. In fact, sand can harbor all kinds of pathogens and even other health threats (e.g. glass fragments and hematophagous flies, some of which are vectors of zoonoses).

Currently, the bathing water regulation is based on the World Health Organization's "Guidelines for safe recreational water environments", published in 2003 (WHO – World Health Organization, 2003). These guidelines recommend a limit of 200 enterococci to accept a 5% risk of developing an ailment associated with human fecal pollution during bathing. While fungi are not mentioned *per se* in the guidelines, they may be included in the equation to determine 5% risk of ailment. On the other hand, management of sand contamination is not included in the guidelines or subsequent regulations, even implicitly. The concept of sand contaminants is pointed out in chapter 6 of the guidelines (where even fungi are addressed) but without any actual conclusions or recommendations of parameters and respective levels. There has been a considerable amount of work published with results and discussions on the *raison d'être* of looking at contaminants in sand. In September 2014, a meeting in Lisbon, Portugal gathered professionals of several areas of expertise to discuss the most sensible approach for sand contaminant analyses, amongst other microbiological public health issues. Up for discussion were parameters, their limits, analytical methods and sampling representativeness as they relate to monitoring sand contamination. The group included bacteriologists, virologists, medical mycologists, and parasitologists both as scientists and technical staff, public health professionals, and beach managers. The outcome of that meeting was a white paper authored by a smaller group of participants who published the meeting's observations and recommendations (Solo-Gabriele *et al.*, 2016). Table 1 lists those.

The group discussion focused on water environments but many of the recommendations are also valid for other sand environments, like sandboxes and recreational parks (see Section "Sandboxes"). The proposed structure for fungal analysis is a simple test based on undifferentiated colony count that can be performed in any water microbiology lab, unless there is reason to specifically identify or detect a species, like an overwhelming presence or outbreak. This requires a reference laboratory or at least an accredited procedure because the recent taxonomic revolution that is taking place in medical mycology, together with emerging anti-fungal resistance, makes the correct identification of fungi a detail of importance, especially during an outbreak.

Table 1 Observations and recommendations of the white paper addressing sand microbial contaminants

Observations

Beaches are a significant contributor to the pathogen load to which beach users are exposed.
At beaches not impacted by sewage, the source of pathogens originates from the local site and includes human visitors, animals, local runoff and the release of microbes from sand.
Studies have identified the presence of pathogens in sand and factors other than point source pollution that contribute to their presence (e.g. moisture, wrack, wildlife, domestic animals, beach morphology, currents).
Epidemiological studies have shown that children who play in sand are subject to higher rates of illness than those not playing in sand.
Measurements of fungi have not been included in beach epidemiological studies.
Considerable evidence exists that sand can serve as a reservoir of enteric microorganisms and fungi, which can be vehicles of disease transmission.
Highlight: Contaminated sands present health and economic costs that can and should be known by decision makers, communities and by individuals.

Recommendations

Identification of recreational beach areas.
Identification of disease-causing agent(s) (viruses, bacteria, fungi and protozoa).
Sampling strategy, control and monitoring programmes.
Methods that estimate risks from pathogens in the sand.
Assessment of exposure to microbes in the sand by contact, ingestion and inhalation.
Tools for identification of sources of microbes.
Evaluation of alternative fecal indicator organisms, to determine the presence of sewage and human waste.
Detection and quantification of microbe levels for specific pathogens with culture-based methods, q-PCR and beach metagenomes.
Determination of whether FIOs are indicative of fecal pollution that carries pathogens or if they have separated from their original source through survival and regrowth.
Development of regulatory standards that reflect microbial sources, pathogens they contain, and associated health risks.
Development of reliable sand collection methods since pathogen contamination at sandy beaches tends to be patchy.
Determination of beach sand quality at freshwater vs. marine beaches.
Assessment of beach sand quality based on contamination by land and air.
Creation of standardized methods to recover and disinfect pathogens from different types of sands.

Highlight: Available evidence should be evaluated by both scientists and regulators with a view to filling the data gaps, which should be followed by sound policy development for safeguarding public health.

Note: Adapted from Romão, D., Sabino, R., Veríssimo, C., *et al.*, 2015. Children and sand play: Screening of potential harmful microorganisms in sandboxes, parks, and beaches. Current Fungal Infection Reports 9, 155–163.

The relevance of sand as an exposure setting in beach and public health was confirmed by Heaney *et al.* (2012) with a controlled epidemiological study of 4,999 beach users and 144 wet sand samples tested for F+ coliphage, *Enterococcus*, *Bacteroidales*, fecal *Bacteroides*, and *Clostridium* spp. The study confirmed an increase in gastrointestinal illness associated with playing in sand on a beach. Although raising awareness to the confirmation of sand as an exposure vector at a beach, the study did not include other microbes or dry sand. Although fungi are known to be plated also directly from water, it is in the dry sand that most of the fungal contaminants can be found, despite the extreme temperatures and solar radiation to which they may be subjected. In fact, some of these fungi, as mentioned above, thrive on radiation. Finding black molds in beach sand seems to be a common situation (Romão *et al.*, 2015). Like other fungal groups, melanised fungi are brought to sand via different carriers – plants, animals, through anthropogenic influences including pollution, and water. However, they do differentiate from others in high concentrations of melanin in their cell walls and unique growth in thick meristematic clumps. Melanin has a protective role against irradiation, but also uses radiation to produce energy and thus helps fixate the micronutrients necessary for fungal development (Dadachova *et al.*, 2007; Dadachova and Casadevall, 2008). Thus, melanised fungi like *Trimmatostroma*, *Exophiala*, *Coniosporium*, *Phaeotheca*, and *Lichenothelia*, are often found on dry solid rocks, covered with salts and exposed to UV radiation (Sterflinger, 1998).

Extremophiles, such as the genera *Hortaea* and *Wallemia* have been isolated from salterns and are frequently present in ponds with high concentrations of salt. Prolonged exposure to those fungi was described as *tinea nigra*, where *Hortaea werneckii* grew on palms of salt harvesting workers. Occasional exposure can be related to spa treatments where mud from salterns is used. While *Hortaea* is widely present in seawater and sand, other black yeasts, such as *Cladophialophora*, *Aureobasidium*, and *Exophiala* likely occur more locally in association with the presence of long-chained hydrocarbons, namely oils and their derivatives (Prenafeta-Boldú *et al.*, 2006; Isola *et al.*, 2013). Also, *Aureobasidium* and *Exophiala* at beaches in Greece have been associated with geochemical properties of sand (Efstratiou and Velegraki, 2009).

How relevant are fungi at the beach, in terms of exposure? Nobody knows. The most common dermatophytes and the most commonly found yeast in human infections, *Candida albicans*, do not seem to survive the heat of the sand at a sunny beach. They sometimes can be found in highly populated beaches, suggesting a recent contamination of anthropogenic origin, rather than resilience. This does not exclude the chance of a transfer between individuals before inactivation, nor does it exclude less sunny beaches that may foster longer survival times. More work is needed in order to assess the actual risk of fungal ailments of recreational beach users.

Also, if we want to consider looking into a possible outbreak, how do we know that the number of cases isolated from recreational beach users did not contaminate the sand, rather than being contaminated by the sand? Fungal outbreaks are usually slow and scattered, with low numbers of cases. They are not explosive like those associated with viruses and certain bacteria. Many patients may have been infected during their holidays and then go home before the onset of the symptoms, rendering the connection between a beach visit and infection unlikely to be found. Residents can be screened during a bathing season, but the local area includes many other possible indirect contamination surfaces/media besides beach sand. It is thus extremely difficult to find an outbreak, unless obvious in a geographically confined yet relevant number of cases. But there may be an alternative to detection, based on modeling of expectations and Quantitative Microbial Risk Assessment (QMRA), as described later in this chapter.

Water Sports

Water related sports may represent excellent relaxation activities, but can also be dangerous. They are often associated with superficial injuries, and in more serious cases, deep trauma, or even drowning; which can represent risk factors for several fungal infections. Fungi posing risks to people involved in water sports are species of *Cylindrocarpum*, *Microsporium*, *Phialemonium*, *Rhinochladia*, and zygomycetous genera *Rhizopus*, *Mucor*, *Lichtheimia*, *Cunninghamella*, *Rhizomucor*, and *Saksenaea* (Novak Babič *et al.*, 2018). These fungi have been associated with a variety of infections from localized to disseminated, depending on the host's immune system. Fungi clearly connected to water-transmitted disease are those of *Scedosporium apiospermum* complex causing near-drowning syndrome, with characteristic cerebral abscesses or pulmonary infection developed after weeks of exposure.

In some areas of the globe, endemic fungi may be a problem for water sports. Sipsas and Kontoyiannis (2008) ran a meta-study to review cases of invasive fungal infections (IFI), looking into the lifestyle and contexts of the patients and concluded in terms of water sports in endemic areas for *Blastomyces* spp., that there is a certain amount of risk associated with the activity.

Cave Exploration

In 2018, a group of 12 members of a junior football team and their assistant-coach went cave exploring in Thailand and heavy rains caused a landslide trapping them in the cave for 17 days. Once rescued, they were all quarantined in an isolation room because of any potential infections myriad pathogens that can be transmitted in caves: Marburg hemorrhagic fever, leptospirosis (Weil's disease), rabies, borreliosis (cave fever), melioidosis (Whitmore's disease), and histoplasmosis (Gorvett, 2018).

Bats inhabit caves and their excreta, named guano, is a breeding ground for many micro- and macroorganisms. Bat guano inside caves in endemic areas for *Histoplasma capsulatum* pose an infection threat by this fungus. The fungus causes histoplasmosis, also known as "cave disease", and is well known in North and Central America as a cause of pneumonia. This histoplasmosis is often misdiagnosed, which leads to an inappropriate therapeutic approach with antibiotics. Immunocompetent individuals have

about a 5% chance of developing the disease when exposed to environmental levels of the fungus. These odds change to between 50% and 100% chance of getting the infection when exposed to higher levels of the fungus, like in caves.

Histoplasmosis has a second, disseminated, stage of the disease, which can happen many years after the primary infection. *H. capsulatum* survives intracellularly in the reticuloendothelial system and may be reactivated mainly (not exclusively) with old age or immune-suppression (Ashbee *et al.*, 2008). Management of the disseminated histoplasmosis, if successful, is achieved by administration of systemic anti-fungal therapy.

In the United States of America, *H. capsulatum* inhabits the soil in the eastern and central parts of the country, especially in the Ohio and Mississippi River Valleys. It is however not exclusive to North and Central America. It has been found in South America, Africa, India, and Southeast Asia (Ashbee *et al.*, 2008).

Gardening and Camping

Gardening is a wonderful opportunity to commune with nature but some of the plants that we deal with have structures that may pierce our skin. *Sporothrix*, the infectious agent causing sporotrichosis, or rose gardener's disease as it is commonly known, is an IFI. *Sporothrix* is one of the most famous agents associated with gardening but also in terms of occupational exposure; it seems to affect people working with tree nursing, garden centers, forestry and hay bale handling (CDC, 2019). Sporotrichosis has a higher prevalence in tropical and temperate climates despite being present in all the world. Japan, India, Mexico, Brazil, Uruguay, Peru, and United States (associated with pine seedlings and moss manipulation (Barros *et al.*, 2011)) are endemic areas for this fungus. *Scopulariopsis brevicaulis*, *Saksenaia vasiformis*, *Scedosporium prolificans*, and *Exophiala jeanselmei* have also been found as minority gardening IFI agents (Sipsas and Kontoyiannis, 2008).

Different species of plants and trees seem to be connected also with symptoms known under the term "farmer's lung disease". The causative agents of the disease are highly irritant spores and mycotoxins wallimidione, wallemineone and walleminol (walleminol A) produced by *Wallemia* spp. These fungi are xerophilic, osmophilic, halophilic, and chaophilic and can thrive on pollen, dry plant material, like hay or leaves, or in the presence of highly concentrated salts or sugars. Spores disperse in large quantities via air during hot and dry weather periods (Zajc and Gunde-Cimerman, 2018).

Lastly, *Cryptococcus gattii sensu lato* is making its way around the world, including Europe, despite being previously considered a tropical and subtropical climate fungus (Hagen *et al.*, 2012). The number of cases is increasing; there are several genotypes known and from those it has been concluded that some of those cases are allochthonous but a high percentage (40%) are autochthonous, many of which are in the Mediterranean region. This yeast can be found in decaying vegetable matter primarily, but it has also been isolated from animals and soil. It can stay dormant in its hosts and manifest itself much later. Unlike its close relative, the opportunistic *Cryptococcus neoformans*, *Cryptococcus gattii sensu lato* is a pathogen. *C. gattii* causes a pneumonia-like infection, with persistent cough, shortness of breath, chest pain and fever and if it spreads to the brain, patients get a cryptococcal meningoencephalitis, experiencing headache, fever, neck pain, nausea, and vomiting, sensitivity to light, confusion or changes in behavior (CDC, 2015). Susceptibility tests *in vitro* suggest that different genotypes react differently to various antifungals. Therapy may involve a combination of Amphotericin B with Fluconazole (Chen *et al.*, 2014) and management may require corticosteroids and draining in order to relieve the intracranial pressure (Franco-Paredes *et al.*, 2015). A more recent approach recommends a triplet of antifungals, lipid Amphotericin B formulation and 5-Flucytosine for 2–6 weeks followed consolidation/maintenance therapy with fluconazole for 12 months or longer.

As mentioned above, *Fusarium* spp. is a common fungus in the ground and care should be taken with rubbing eyes in order to prevent fungal keratitis, by this but also by other fungi. Soil is full of microbes, many of which are fungal opportunists and allergenic taxa, as mentioned above relative to swimming pools (*Alternaria*, *Aspergillus*, *Bipolaris*, *Cladosporium*, *Curvularia*, *Helminthosporium*, *Epicoccum*, *Aureobasidium*, *Penicillium*, *Malassezia*, *Saccharomyces cerevisiae*, and *Trichophyton*). Susceptible campers must take care and avoid camping sites with moist ground in order to avoid turning a camping event into a trip to hell.

Sandboxes

Undoubtedly, where there is sand and there are children, there will be a confluence of both. Children love to build structures on sand, like castles and dams (depending on water availability); they like to dig and even to bury themselves and others, often ending up eating some of the sand. 190 mg/day was the estimate of sand ingested by children without pica (extraordinary tendency to eat sand – van Wijnen *et al.*, 1990) at the beach. There is usually concomitant animal life on sand, especially outside of beach visitation hours. Considering that children get sand on their skin, eyes, ears, hair, nails and mucosae, and that prowling animals, rodents and birds shed whatever they have on their skin besides leaving excreta behind, it is easy to envision why sand should be monitored for pathogens.

Municipalities and public health protection offices have occasionally expressed concerns about microbial contaminants in sandboxes of public parks and beaches. A good example is a publication by European researchers with the result of such worries, in and around Lisbon, on sandboxes from three elementary schools and two kindergartens. The results were unsettling, but not necessarily surprising: "Potentially pathogenic fungi were isolated from all samples besides one. *Fusarium dimerum* (32.4%) was found to be the dominant species in one park and *Chrysosporium* spp. in the other (46.6%). Fourteen different species and genera were detected, and no

dermatophytes were found. Of a total of 14 species and genera, the fungi most isolated from the samples of the elementary schools were *Penicillium* spp. (74%), *Cladophialophora* spp. (38%) and *Cladosporium* spp. (90%). Five dominant species and genera were isolated from the kindergartens. *Penicillium* spp. was the only genus isolated in one, though with remarkably high counts (32,500 colony-forming units per gram). In the other kindergarten *Penicillium* spp. were also the most abundant species, occupying 69% of all the fungi found." (*Fusarium dimerum* has changed to *Bisifusarium dimerum* (Lombard et al., 2015; Viegas et al., 2016)). The authors therefore recommend that sand be cleaned and replaced regularly.

Beach sand was addressed in another heading in this chapter (See Section "Sunbathing"). The different matrices pose different concerns, since the microorganisms at the beach tend to be less concentrated than in sandboxes.

Climate Change – The Game Changer

The days of geographically circumscribed endemic fungal infections are over. Until not many years ago, if you were a physician practicing somewhere in Europe and you got a patient with pneumonia, you would probably not suspect an endemic fungal infection like blastomycosis or histoplasmosis, unless your patient traveled recently to North America and mentioned it. Generally, endemic fungi remain endemic for now, but maintain the potential for changes in range associated with climatic alterations. The problem is that known pathogens and opportunists may experience new niches, displacement or range expansion due to extreme weather events associated with climate change and in concert with globalization (McIntyre et al., 2017). This may include endemic fungi, as already may have happened in the Pacific Northwest region of North America, with a Vancouver Island outbreak caused by *Cryptococcus deuterogattii* which has historically been endemic to tropical and subtropical climates (Kidd et al., 2004). There is still some controversy over the origin of this pathogen, which some authors believe to have originated in a mutant lineage originating somewhere else in the West-coast of North America (Ma et al., 2009). More recently, however, a new taxonomy for this *C. gatii* complex was proposed by Hagen et al. (2015).

There is a known movement of air carrying fungal particles from Africa to America (Kellogg and Griffin, 2003), no doubt associated with the jet streams that flow westbound and converge at the equator. This may have been the cause of propagation of the plant pathogen *Hemileia vastatrix* (Bowden et al., 1971) responsible for coffee leaf rust, a fungal infection devastating entire crops of coffee in South America since 1970. McIntyre et al. (2017) may have focused on the general alterations of climate because of the expansion of high temperatures beyond their usual latitudes. However, together with globalization, extreme weather events are generating the biggest concerns and the strangest clinical cases. The following three examples illustrate the worries about climate change and extreme weather events:

- (1) Central Europe has reported bacterial *Vibrio cholerae* necrotizing fasciitis in bathers of inland water catchments (Hirk et al., 2016);
- (2) There are cases of mucormycosis associated with wood fragments flying at high speeds during hurricane-like winds (Neblett Fanfair et al., 2012);
- (3) A case of mucormycosis associated with catastrophic floods with a near-drowning situation, in Mandra, Attica in Greece, in November 2017 (Sympardi et al., 2019).

Cases like these suggest that public health protection agencies need to advise the public on susceptibility factors more actively during extreme weather events and for climate change preparedness. For that, knowledge gathering is crucial. Benedict and Park (2014) prepared a review on published cases of natural disasters and fungal infections. In this review, coccidioidomycoses were the leading infections with over 100 cases, both in a 1977 dust storm and the 1994 Northridge earthquake in the USA. Many of these kinds of situations, however, take place not only due to natural disasters but frequently in recreational settings (Sipsas and Kontoyiannis, 2008).

Quantitative Microbial Risk Assessment (QMRA)

In a public health context, and especially in the face of climate change and globalization that can lead to changes in fungal contaminant ranges, it will be important to look toward understanding human health outcomes resulting from exposure to fungi. Quantitative Microbial Risk Assessment (QMRA) can be a powerful tool for understanding how contaminant concentrations are related to risks to human health in areas like gardens, beaches, swimming pools, and caves.

QMRA relies upon contaminant concentration data, combined with an expected exposure pathway from the environment to the human host (Fig. 1), to determine the concentration (exposure dose) of contaminants that humans are likely to be exposed to during their activities. From there, QMRA applies that calculated exposure dose to an existing dose-response model. This model then predicts the probability of a health response (e.g., infection, illness, death, etc.), given the calculated exposure dose (Fig. 2, Haas et al., 2014). This probability of a health response is also known as the "risk" in quantitative microbial risk assessment and can be used to inform management and policy guidance for controlling contamination in the local environment.

Recent research has indicated that bacterial and viral health risks at beaches can be substantial, but that they are also highly dependent upon both the concentration of the bacteria or viruses and the exposure pathway. For instance, it has been found that

Fig. 1 Potential exposure pathways that human and animal hosts may be subject to at the beach. Different colors represent distinct pathways. Dashed lines represent transport of contaminants through the water or sand media; solid lines denote transfer of contaminants between the environment and human or animal hosts. Image created using vector graphics from Tracey Saxby, Kim Kraeer, Lucy Essen-Fishman, Jane Thomas, and Kate Moore, Integration and Application Network, University of Maryland Center for Environmental Science (ian.umces.edu/imagelibrary/) and images of microorganisms from the US Centers for Disease Control and Prevention. Reproduced from Jabra-Rizk, M.A., Falkler, W.A., Meiller, T.F., 2004. Fungal biofilms and drug resistance. *Emerging and Infectious Diseases* 10 (1), 14–19. doi:10.3201/eid1001.030119.

Fig. 2 General flow of development for a QMRA. Contaminant concentration observations are used in hazard identification and exposure assessment, while exposure pathways from the environment to human hosts are used in the exposure assessment. Epidemiological or feeding study observations are used with exposure assessment results in the dose-response modeling process, to calculate overall risk.

contaminant concentrations can be much higher in sand than in recreational water (Heaney *et al.*, 2012), due to the accumulation of contaminants in biofilms (Piggot *et al.*, 2012). However, the overall health risks associated with sand contamination may be comparable to or less than those associated with water contact because of the more complex exposure pathways that sand contaminants must take to infect humans.

A variety of QMRAs have been developed for recreational water in beach settings (Dickinson *et al.*, 2013; Eregno *et al.*, 2016; Juntunen *et al.*, 2017; Shibata and Solo-Gabriele, 2012; and others) and swimming pools (Peters *et al.*, 2017). These risk assessments, however, are exclusively in the context of contamination by bacteria or viruses; there is very little risk assessment work that is focused on fungal contamination in recreational areas. QMRAs developed for mycotoxin in agricultural environments

(Wu, 2004; Han *et al.*, 2013) may provide examples to draw from in developing fungal QMRAs for recreational settings. However, their applicability is limited because of the sensitivity of human health outcomes and risks to differences in both the microbial taxon and the setting/exposure pathway. It will therefore be crucial for ongoing research to focus on characterizing exposure pathways and developing epidemiologically-based dose-response models for fungal contaminants in areas like beaches, swimming pools, spas, gardens, and caves.

Conclusion

Currently, there is a rising awareness of the global burden of fungal infections. Bongomin *et al.* (2017) estimated nearly 2 billion people are suffering from a hair, skin or nail infection and tens of millions of from mucosal candidosis. They also describe the main fungal agents responsible for these infections at a global scale: “Although the epidemiology of fungal diseases has greatly changed over the past few decades, *Aspergillus*, *Candida*, *Cryptococcus* species, *Pneumocystis jirovecii*, endemic dimorphic fungi such as *Histoplasma capsulatum* and *Mucormycetes* remain the main fungal pathogens responsible for the majority cases of serious fungal disease. *Candida albicans* is the main agent responsible for mucosal disease, *Aspergillus fumigatus* for most allergic fungal disease and *Trichophyton* spp., especially *T. rubrum*, for skin infections.” According to the same study, 150 million people suffer from serious fungal infection. Many of which are in less healthy economies but serious fungal infections have one common denominator throughout the whole world: the survival rate of the patient starts, *grosso modo*, at 50% and ends in 0% (Hagen, 2018). Mortality is currently over 1.6 million, which is similar to tuberculosis and three times that of malaria. Despite these numbers, there is no policy to fight fungal infections by health authorities anywhere but the WHO recently included two pathologies in the tropical neglected diseases list: Chromoblastomycosis and Mycetoma (WHO – World Health Organization, 2016).

One of the weak points in public policy management of fungal infections is neglecting their treatment rate and not considering fungi as a group of diverse pathologies and infection agents. This posture would make sense considering that all fungal infections are handled with a handful of antimicrobial agents and approaches. The biochemistry of our cells, of protozoan parasites and of fungi is very similar due to small evolutionary distances, so there are not many options for selectively treating an infection, leaving the patient unharmed.

The best policy in public health protection from fungal infections is by preventing them instead of managing or treating them, given the low treatment efficacies. However, it has been called a neglected epidemic (Armstrong-James *et al.*, 2014) in the particular context of HIV/AIDS patients but likely for others as well.

This chapter focused on exposure in leisure contexts, and the main goal of the authors is to raise awareness for the possible fungal ailments associated with leisure activities in the most common practices and contexts, because awareness leads to prevention and management.

Introduction

High levels of fungal particles can be found in various occupational settings making workers to be exposed to these micro-organisms and their components, such as viable and non-viable spores or conidia and hyphal fragments for considerably long periods of time, thus increasing the risk for occupational respiratory diseases (Eduard, 2008).

Aspergillus can be found in almost every environment since they are ubiquitous in the environment and easily disseminated in the air (Sabino *et al.*, 2019). The *Aspergillus* genus is characterized by its filamentous fungi with septate hyphae and with specific reproductive structures of this genus that are the conidia (Park and Mehrad, 2009). Among *Aspergillus* genus, the designations actually represent sections (or complexes) of closely related species (also referred to as cryptic species) that cannot be clearly distinguished morphologically (Lamoth, 2016).

Among *Aspergillus* genus, *Aspergillus* section *Fumigati*, is one of the main responsible for invasive aspergillosis and other considerable risk factors (Baddley, 2011). This fungus has bluish-green colonies and has a high growth rate (Xavier *et al.*, 2006). *Aspergillus* section *Fumigati* is a thermophilic species with growth rates that occur even at high temperatures (55°C) and can guarantee its survival at temperatures around 70°C (Fritzler *et al.*, 2007; Albrech *et al.*, 2010; Pohl *et al.*, 2011). In most cases this species can be isolated from a wide variety of substrates and at temperatures in between 12°C and 70°C. However, it is at a temperature of 37°C and at a pH of 3.7–7.6 that it has an optimal growth rate (Kozakiewicz and Smith, 1994).

Aspergillus section *Fumigati* is a natural recycler, as this fungus has a very versatile metabolism that allows it to meet all its nutritional requirements under the most diverse environmental conditions (Gibbons *et al.*, 2012). It has enzymes in its constitution that allows to obtain nitrogen and other compounds through the degradation of plant cells (Tekaiia and Latgé, 2005; Abad *et al.*, 2010). This ability allows this fungus to respond to nutritional restrictions, but also to a physiological versatility for the use of different substrates to obtain nutrients. Thus, *Aspergillus* section *Fumigati* can compete with other fungi and bacteria in the environment (Anastasi *et al.*, 2005). Given these characteristics, it is quite common to find this type of fungi in places that contain a lot of organic matter, such as gardens, greenhouses or even in composting areas, in these cases the percentage of this species present in the environment can be around 35%–75% (Anastasi *et al.*, 2005). In addition to these saprophytic environments, this fungus can also express other virulence factors that allow it to adhere and invade host cells, survive in environments of hypoxia and nutritional scarcity, such as the lung environment (Panepinto *et al.*, 2003; Schrettel *et al.*, 2004; Moreno *et al.*, 2007; Willger *et al.*, 2008; Liu *et al.*, 2010; Gravelat *et al.*, 2013; Bertuzzi *et al.*, 2014; Pongpom *et al.*, 2015; Liu *et al.*, 2016).

Some specific characteristics make this fungus an omnipresent pathogen, such as: its high capacity for survival and proliferation in a wide variety of environments, great efficiency of dispersion mainly in the air, because its conidia have physical characteristics that provide the ability to reach the distal airways (Brakhage and Liebmann, 2005; Rhodes, 2006) and the ability to adapt to their host's environment (Latgé, 2001; Anastasi *et al.*, 2005; Tekaiia and Latgé, 2005; Hohl and Feldmesser, 2007; Dagenais and Keller, 2009; Abad *et al.*, 2010). These characteristics make *Aspergillus* section *Fumigati* a very competitive fungus, where the temperature, pH and nutrients are not ideal for a wide spectrum of microorganisms. It is in these environments that *Aspergillus* section *Fumigati* thrives due to the lack of competition in the environment, making this fungus an excellent opportunistic pathogen (Latgé, 2001).

This species is considered the major cause of invasive aspergillosis that represents a danger to human life, as this is a saprophytic fungus that is present in most environments, and in this way causing human exposure to *Aspergillus* section *Fumigati* almost daily. This type of infections is initiated by inhalation of conidia, which in a normal situation are quickly eliminated from the host organism, however in the case of immunocompromised individuals it can be the cause of invasive mycosis (Rhodes, 2006; Kwon-Chung and Sugui, 2013).

To access its presence in the environment active methods can be applied, usually by the use of devices that sample air through impaction, impingement or filtration methods (Mandal and Brandl, 2011; Viegas *et al.*, 2015). Passive sampling methods can be also applied and provide an assessment of the harmful part of the airborne population that accumulates on a surface (French *et al.*, 1980; Pasquarella *et al.*, 2000).

Azoles are currently considered the first-line drugs to combat the fungal presence, as they act directly on the production of ergosterol, which is an essential constituent of the fungal cell membrane and its consistency (Diaz-Guerra *et al.*, 2003). In the last

15 years, this type of drugs has maintained a prominent position regarding the treatment and prevention of diseases originating in the genus *Aspergillus* (Patterson *et al.*, 2016). It is scientifically reported that resistance to this type of drugs may be an intrinsic phenotype of the *Aspergillus* genus, more specifically in the case of *Aspergillus* section *Fumigati*. The acquisition of this capacity may be due to exposure to fungicides in agricultural areas or in a clinical environment (Denning *et al.*, 1997; Verweij *et al.*, 2007; Van der Linden *et al.*, 2011; Meis *et al.*, 2016). Currently, resistance to azoles is already reported in environmental isolates from *A. fumigatus* (Snelders *et al.*, 2008; Jeanvoine *et al.*, 2017; Viegas *et al.*, 2020).

Additionally, *Aspergillus* section *Fumigati* produces a variety of secondary metabolites that can alter the function of the host cells and thus contribute to their virulence. The genome of this fungus has approximately 34 gene groups that can express these secondary metabolites, of these few have been extensively studied (Ingliš *et al.*, 2013). Among all of them, the metabolite of *A. fumigatus* best documented is gliotoxin, this toxin has multiple effects on the host, from damage to the respiratory epithelium, production of reactive oxygen species, inhibition of phagocytosis, or even the apoptosis of the immune system cells (Mullbacher *et al.*, 1985; Amitani *et al.*, 1995; Pahl *et al.*, 1996; Stanzani *et al.*, 2005; Orciuolo *et al.*, 2007; Liu *et al.*, 2018).

It is reported in several studies that the inhalation of particles contaminated with fungi or bio-components produced by them can lead to the contraction of allergic reactions and the development of respiratory diseases (Macher *et al.*, 1999). In the literature, it is also reported that these components present in aerosolized particles can cause asthma, allergic alveolitis, toxic organic dust syndrome, byssinosis, chronic bronchitis, allergic rhinitis, mucosal irritation, sick building syndrome, chronic fatigue syndrome, aspergillosis, other infectious diseases and even cancer (Dutkiewicz and Górny, 2002; Krysińska-Traczyk *et al.*, 2003; Jahnz-Rozyk *et al.*, 2011).

This issue is of great importance, especially for occupational and indoor environments, that were already reported to have high levels of azole-resistant *Aspergillus* isolates that may result in an increased occupational risk and in difficult clinical management (Chowdhary *et al.*, 2013; Snelders *et al.*, 2008; Verweij *et al.*, 2013).

Thus, a correct intervention to assess occupational exposure to *Aspergillus* section *Fumigati* is of utmost importance for the risk characterization and management. This study intends to perform a systematic search review, to verify which methods for sampling and analyses are currently used by the scientific community and to discuss which of them present more accurate results.

Materials and methods

This study was based on a systematic search for information and data that have been published in free access sources during the period of 1st January 2000 to 31st December 2020. In order to comply with the rigor of demand, specific parameters were established to assist in the search for information in order to identify and select articles related to occupational environments where the search for *Aspergillus* section *Fumigati* is carried out. The search terms were carried out in the selected database (PubMed), in English and giving preference to articles that focused on *Aspergillus* section *Fumigati* assessment in occupational environments. This research resulted in 25 articles from PubMed, all articles that were not accepted by the inclusion criteria were excluded (Table 1).

The selection of articles was elaborated in a structured way with different phases throughout the process. All the steps are described in the following diagram (Fig. 1).

Results

A total of 25 articles related to occupational environments were included and analyzed (Hospital environments, farms, animal production and composting were the most common environments). Sampling methods assays, species identification and the main findings were analyzed. Most of the studies analyzed were carried out on farms (10 out of 25). The remaining were carried out in hospital environment (7 out of 25), composting stations (4 out of 25), archives (2 out of 25), a biodiesel plant (1 out of 25) and in flower fields (1 out of 25).

Table 1 Inclusion and exclusion criteria for the selected articles

Inclusion criteria	Exclusion criteria
Articles published in the English language;	Articles published in other languages
Articles published from 1st January 2000 to 31st December 2020	Articles published prior to 2000
Articles published in any country	
Articles on <i>Aspergillus fumigatus</i> in occupational environments	Articles related exclusively to biological samples from workers
Identification of <i>Aspergillus</i> section <i>Fumigati</i>	<i>Aspergillus fumigatus</i> not identified in the study
Original scientific articles on the topic	Abstracts of congress, reports, reviews/state of the art articles

Fig. 1 Article selection based on the PRISMA method.

The most frequent sampling strategy among all the studies analyzed was the exclusive use of active sampling methods (11 of 25). However, although the use of passive methods was lower, their use was verified with some frequency (7 of 25). The combined use of the two types of sampling was also found in 7 studies (Zielinska-Jankiewicz *et al.*, 2008; Madsen *et al.*, 2012; Caggiano *et al.*, 2014; Madsen *et al.*, 2015; Viegas *et al.*, 2016a; Demuyser *et al.*, 2019; Madsen *et al.*, 2020). The most used active sampling method was air sampling through impaction method (Augustowska and Dutkiewicz, 2006; Zielinska-Jankiewicz *et al.*, 2008; Gniadek *et al.*, 2011; Ross *et al.*, 2011; Chang *et al.*, 2013; Caggiano *et al.*, 2014; Martínez-Herrera *et al.*, 2016; Rudramurthy *et al.*, 2016; Viegas *et al.*, 2016a; Demuyser *et al.*, 2019), but the method of sampling air by filtration was also widely used (Skórska *et al.*, 2005; Mackiewicz and Szponar, 2009; Timm *et al.*, 2009; Madsen *et al.*, 2012; Chang *et al.*, 2013; Madsen *et al.*, 2015; Priyamvada *et al.*, 2017; Madsen *et al.*, 2020). Regarding passive methods, the collection of bulk samples was the most observed approach (Storm *et al.*, 2010; Madsen *et al.*, 2012; Queiroz *et al.*, 2013; Carvalho *et al.*, 2016; Alvarez-Moreno *et al.*, 2017; Trovato *et al.*, 2018; Schoustra *et al.*, 2019) but surface sampling (Zielinska-Jankiewicz *et al.*, 2008; Caggiano *et al.*, 2014; Demuyser *et al.*, 2019; Madsen *et al.*, 2020) and settled dust sampling (Madsen *et al.*, 2015; Skóra *et al.*, 2016) were also used.

As for the analytical procedures, the exclusive use of culture-based methods was observed in 8 of the 25 studies (Skórska *et al.*, 2005; Augustowska and Dutkiewicz, 2006; Zielinska-Jankiewicz *et al.*, 2008; Gniadek *et al.*, 2011; Ross *et al.*, 2011; Caggiano *et al.*, 2014; Martínez-Herrera *et al.*, 2016; Rudramurthy *et al.*, 2016), while the exclusive use of molecular tools was not verified. The combined use of culture-based methods and molecular tools was the most common scenario (16 out of 25) (Prigione *et al.*, 2004; Mackiewicz and Szponar, 2009; Timm *et al.*, 2009; Storm *et al.*, 2010; Madsen *et al.*, 2012; Chang *et al.*, 2013; Queiroz *et al.*, 2013; Carvalho *et al.*, 2016; Skóra *et al.*, 2016; Viegas *et al.*, 2016a; Alvarez-Moreno *et al.*, 2017; Priyamvada *et al.*, 2017; Trovato *et al.*, 2018; Demuyser *et al.*, 2019; Schoustra *et al.*, 2019; Madsen *et al.*, 2020). Overall, culture-based methods were the most frequent approach verified in all of the 25 studies (Prigione *et al.*, 2004; Skórska *et al.*, 2005; Augustowska and Dutkiewicz, 2006; Zielinska-Jankiewicz *et al.*, 2008; Mackiewicz and Szponar, 2009; Timm *et al.*, 2009; Storm *et al.*, 2010; Gniadek *et al.*, 2011; Ross *et al.*, 2011; Madsen *et al.*, 2012; Chang *et al.*, 2013; Queiroz *et al.*, 2013; Caggiano *et al.*, 2014; Madsen *et al.*, 2015; Carvalho *et al.*, 2016; Martínez-Herrera *et al.*, 2016; Rudramurthy *et al.*, 2016; Skóra *et al.*, 2016; Viegas *et al.*, 2016a; Alvarez-Moreno *et al.*, 2017; Priyamvada *et al.*, 2017; Trovato *et al.*, 2018; Demuyser *et al.*, 2019; Schoustra *et al.*, 2019; Madsen *et al.*, 2020), followed by the use

Table 2 Data obtained from the chosen articles

Title	Country	Environmental description	Objective	Sampling methods	Analytic methods	Range/Prevalence	Main findings	References
<i>Development and Use of Flow Cytometry for Detection of Airborne Fungi</i>	Italy	1 Composting plant, 1 forest, 1 damp dwelling	Develop an analysis method based on FCM for rapid quantification of fungal load	Air sampling by impinger	Culture-based methods, FCM	Microscopy: 3.46×10^4 CFU m ⁻³ – 7.70×10^5 CFU m ⁻³ FCM: 3.80×10^4 CFU m ⁻³ – 5.30×10^5 CFU m ⁻³ <i>Aspergillus</i> section <i>Fumigati</i> gave R ² values of 0.97 and 0.99 in the first and second simulated tests.	The degree of correlation between the FCM and microscopy counts was quite high. The use of flow cytometry proved to be feasible and more accurate than microscopy, however it was only used for the total load in the environment and requires further investigation.	Prigione <i>et al.</i> (2004)
<i>Exposure to airborne microorganisms, dust and endotoxin during processing of valerian roots on farms</i>	Poland	15 Valerian root farms	Assess the level of microorganisms present in this type of farms	Air sampling by personal and stationary filtration	Culture-based methods	Total fungi: 0.15 CFU m ⁻³ – 1.35×10^5 CFU m ⁻³ <i>Aspergillus</i> section <i>Fumigati</i> isolated: 57.5%	The prevalence of <i>Aspergillus</i> section <i>Fumigati</i> is only verified after the roots are dried, this being one of the main dangers encountered due to the risks it poses to the respiratory system.	Skórska <i>et al.</i> (2005)
<i>Variability of airborne microflora in a hospital ward within a period of one year</i>	Poland	1 Pulmonology ward	Study the variability of the microflora present in the air of a pulmonology ward for 1 year	Impaction air sampling	Culture-based methods	Total fungi: 9.9 CFU m ⁻³ –96.1 CFU m ⁻³ <i>Aspergillus</i> section <i>Fumigati</i> isolated: 77%	<i>Aspergillus</i> section <i>Fumigati</i> proved to be the most prevalent fungus among all observed fungi The study showed that exposures to these fungi add to respiratory complications and contribute to sick building syndrome.	Augustowska and Dutkiewicz (2006)
<i>Microbiological contamination with molds in work environment in libraries and archive storage facilities</i>	Poland	3 Archives e 1 Library	Evaluate microbiological contamination in libraries and archives	Impaction air sampling, surface sampling with contact plates	Culture-based methods	Total fungi: 20 CFU m ⁻³ – 2.9×10^3 CFU m ⁻³ <i>Aspergillus</i> section <i>Fumigati</i> : 80 CFU m ⁻³ – 5.0×10^2 CFU m ⁻³	Although visible signs of contamination were not verified, the study revealed the presence of allergenic and toxigenic species, such as <i>Aspergillus</i> section <i>Fumigati</i> , and some of these species exceeded reference values for occupational environments.	Zielinska-Jankiewicz <i>et al.</i> (2008)
<i>Respiratory disorders in two workers of customs depositories occupationally exposed to moldy tobacco</i>	Poland	2 Tobacco warehouses	Develop a microbiological assessment of potential health hazards in the workplace	Air sampling by filtration	Culture-based methods, GC-MSMS	Total fungi: 110 CFU m ⁻³ –310 CFU m ⁻³ <i>Aspergillus</i> section <i>Fumigati</i> isolated: 41.9%–70%	Professionals in this area are exposed to fungi, especially those of the genus <i>Aspergillus</i> and <i>Penicillium</i> , which due to the poor ventilation in the environment and presence of nutrients proliferate and easily aerosolize.	Mackiewicz and Szponar (2009)
<i>Assessment of the Total Inflammatory Potential of Bioaerosols by Using a Granulocyte Assay</i>	Denmark	22 Biodiesel plants	Develop a fast and low-cost method for microbiological analysis of bioaerosols in occupational environments	Air sampling by filtration	Culture-based methods, NAGase analysis	<i>Aspergillus</i> section <i>Fumigati</i> : BD– 4.4×10^4 CFU m ⁻³	The analysis of reactive oxygen species gives reliable information on the inflammatory potential of bioaerosols present in a given environment.	Timm <i>et al.</i> (2009)

<i>Dynamics in the microbiology of maize silage during whole-season storage</i>	Denmark	20 Dairy farms	Monitoring of microbiological variations in different seasons	Collection of corn silage	Culture-based methods	Total fungi: $\pm 1 - \pm 2.5$ log CFU g ⁻¹ <i>Aspergillus</i> section <i>Fumigati</i> : 11%–60%	There is a great variation of the fungi present between periods. The storage of corn for long periods is the main cause of changes in the mycobiota.	Storm <i>et al.</i> (2010)
<i>Cytotoxicity of Aspergillus Fungi Isolated from Hospital Environment</i>	Poland	Hospital rooms	To evaluate the cytotoxicity of fungi of the genus <i>Aspergillus</i> isolated from hospital environments	Impaction air sampling	Culture-based methods	Total fungi: 5 CFU m ⁻³ – 2.37×10^3 CFU m ⁻³ <i>Aspergillus</i> section <i>Fumigati</i> isolated: 37%	Most of the <i>Aspergillus</i> tested were cytotoxic. Ambient temperatures are favorable for the survival of these species and the production of metabolites.	Gniadek <i>et al.</i> (2011)
<i>Refurbishment works in a hospital during normal operation</i>	Germany	2 Surgical wards and 1 Intensive care area	Monitor the fungal load and particulate matter after infiltrations	Impaction air sampling	Culture-based methods	Total fungi: < 10 CFU m ⁻³ – 3.6×10^2 CFU m ⁻³ <i>Aspergillus</i> section <i>Fumigati</i> isolated: 0%	Although there is an increase in the number of particles in the restoration period, the number of viable fungi did not show to be influenced by the works, but by the type of affluence that the rooms have in terms of staff, patients or family members.	Ross <i>et al.</i> (2011)
<i>Organic dust toxic syndrome at a grass seed plant caused by exposure to high concentrations of bioaerosols</i>	Denmark	2 Grass seed factories	Assess the relationship between ODTs and the management of grass seeds	Collection of seed samples, air sampling by filtration	Culture-based methods	<i>Aspergillus</i> section <i>Fumigati</i> : 9.0×10^3 CFU kg ⁻¹ – 4.50×10^9 CFU kg ⁻¹	Microorganisms were aerosolized 10 ⁷ times more in problematic seeds than in reference seeds Respiratory protective equipment has proven to be efficient and should be used at all times.	Madsen <i>et al.</i> (2012)
<i>Bioaerosols from a Food Waste Composting Plant Affect Human Airway Epithelial Cell Remodeling Genes</i>	Taiwan	1 Composting station	Evaluate the distribution of microorganisms in a composting station	Air sampling by filtration and impaction	Culture-based methods, PCR	<i>Aspergillus</i> section <i>Fumigati</i> : 1×10^2 CFU m ⁻³ – 1×10^6 CFU m ⁻³	The levels of <i>Aspergillus</i> section <i>Fumigati</i> found are not an effective indicator for monitoring workers 'health, underestimating the impact on these workers' health.	Chang <i>et al.</i> (2013)
<i>Fungal contamination and determination of fumonisins and aflatoxins in commercial feeds intended for ornamental birds in Rio de Janeiro, Brazil</i>	Brazil	Poultry feed industries	Determine mycobiota distribution and quantify mycotoxins in poultry feed	Collection of feed samples	Culture-based methods	Total fungi: 100 CFU g ⁻¹ – 2.9×10^6 CFU g ⁻¹ <i>Aspergillus</i> section <i>Fumigati</i> isolated: 36%	Several toxigenic species have been identified, with <i>Aspergillus</i> section <i>Fumigati</i> being among the most prevalent species.	Queiroz <i>et al.</i> (2013)
<i>Mold contamination in a controlled hospital environment: a 3-year surveillance in southern Italy</i>	Italy	5 Intensive care units	Analyze the presence of molds in the air and on the surfaces of operating theaters and controlled environments	Impaction air sampling, surface sampling with contact plates	Culture-based methods	Surfaces Total Fungi: 0 CFU cm ⁻² –0.35 CFU cm ⁻² <i>Aspergillus</i> section <i>Fumigati</i> isolated: 20% Air sampling Total Fungi: 80 CFU m ⁻³ –187 CFU m ⁻³ <i>Aspergillus</i> section <i>Fumigati</i> isolated: 28.6%–76.2%	The most contaminated location in these intensive care units was the oncology pediatric area, largely due to the presence of visitors, animators or family members Areas that have undergone construction or are under reconstruction show higher concentrations of <i>Aspergillus</i> in the air, due to the resuspension of particles.	Caggiano <i>et al.</i> (2014)
<i>Microbial diversity in bioaerosol samples causing ODTs compared to reference bioaerosol samples as measured using</i>	Denmark	1 Grass seed factory	Check the microbiological communities present in problematic and	Air sampling by personal filtration, collection of dust samples	Culture-based methods, MALDI-TOF, PCR, NGS	<i>Aspergillus</i> section <i>Fumigati</i> on workers: 1.48×10^6 CFU m ⁻³ – 2.10×10^6 CFU m ⁻³ <i>Aspergillus</i> section <i>Fumigati</i> on seeds:	Determination of microbiological profiles can be performed when using MALDI-TOF, 98% of the species identified in culture-based methods could be identified through MALDI-TOF.	Madsen <i>et al.</i> (2015)

(Continued)

Table 2 Continued

Title	Country	Environmental description	Objective	Sampling methods	Analytic methods	Range/Prevalence	Main findings	References
<i>Illumina sequencing and MALDI-TOF</i>			non-problematic seeds			7.50×10^5 CFU m^{-3} – 9.00×10^6 CFU m^{-3}		
Occurrence of mycotoxins and yeasts and molds identification in corn silages in tropical climate	Brazil	36 Corn silos	Identify fungi and detect mycotoxins in corn silos	Collection of corn samples	Culture-based methods, Rep-PCR	Total fungi: 2.60 log CFU g^{-1} –3.84 log CFU g^{-1} <i>Aspergillus</i> section <i>Fumigati</i> isolated: 41.7%	All samples in which <i>Aspergillus</i> section <i>Fumigati</i> fungal growth was found can be isolated.	Carvalho <i>et al.</i> (2016)
Fungal diversity and <i>Aspergillus</i> species in hospital environments	Mexico	2 Hospitals	Assess the fungal diversity present in 2 hospitals	Impaction air sampling	Culture-based methods	Total fungi: 8.53 CFU m^{-3} –85.98 CFU m^{-3} <i>Aspergillus</i> section <i>Fumigati</i> isolated: $\pm 5\%$ – $\pm 10\%$	The most abundant species in both hospitals are also clinically relevant. The thermal tolerance phenotypic characteristic of species belonging to the <i>Fumigati</i> section was confirmed.	Martínez-Herrera <i>et al.</i> (2016)
High fungal spore burden with predominance of <i>Aspergillus</i> in hospital air of a tertiary care hospital in Chandigarh.	India	1 Tertiary care hospital	Study the mycoflora of areas with A/C and without A/C	Impaction air sampling	Culture-based methods	<i>Aspergillus</i> section <i>Fumigati</i> spores: 0–63.6 CFU mm^{-3}	The existence of an A/C system did not show any influence on the levels of fungal contaminants. A uniform distribution of fungal species was verified throughout the seasons due to the tropical climate of India.	Rudramurthy <i>et al.</i> (2016)
Evaluation of Microbiological and Chemical Contaminants in Poultry Farms	Polonia	13 Poultry farms	Assess the chemical and microbiological contamination present in poultry settle dust	Settle dust sampling, gravimetry	Culture-based methods	Total fungi: 1.1×10^5 CFU g^{-1} – 3.2×10^6 CFU g^{-1} <i>Aspergillus</i> section <i>Fumigati</i> isolated: 5.3%	Analyzes of dust, microorganisms and other metabolites suggest that this work environment poses a risk of respiratory complications for its workers. It is advisable to monitor the effectiveness of these workers' respiratory protective equipment.	Skóra <i>et al.</i> (2016)
Occupational exposure to fungi and particles in animal feed industry	Portugal	1 Feed industry	Characterize fungal exposure in different jobs in the fattening industry	Surface swab, Impaction and impinger air sampling	Culture-based methods, qPCR	Surfaces Total Fungi: 0 CFU m^{-2} – 1.8×10^5 CFU m^{-2} <i>Aspergillus</i> section <i>Fumigati</i> isolated: 6.3% Air sampling Total Fungi: 0 CFU m^{-3} –144 CFU m^{-3} <i>Aspergillus</i> section <i>Fumigati</i> isolated: 46.6%	Task-focused exposure assessment provides a better exposure assessment, rather than the personal 8-h continuous assessment. The particles found are able to reach the distal respiratory system, and these are problematic because they can act as a transport and source of nutrients for pathogenic or toxigenic species.	Viegas <i>et al.</i> (2016a)
Azole-resistant <i>Aspergillus fumigatus</i> harboring TR34/L98H, TR46/Y121F/T289A and TR53 mutations related to flower fields in Colombia	Colombia	32 Flower fields	Assess the environmental presence of drug-resistant species	Collection of soil samples	Culture-based methods, analysis of mutations, azole-resistance test	<i>Aspergillus</i> section <i>Fumigati</i> isolated: 20% ^a	Of the eight triazoles registered for floriculture in Columbia 50% of them had no effect on <i>Aspergillus</i> section <i>Fumigati</i> . The study demonstrates the phenotypic resistance present in this species.	Alvarez-Moreno <i>et al.</i> (2017)
Seasonal variation of the dominant allergenic fungal aerosols – One year study from southern Indian region	India	1 University	Investigate the prevalence of 3 fungal species for an entire year	Air sampling by filtration	Culture-based methods, RT-PCR	<i>Aspergillus</i> section <i>Fumigati</i> (copies of DNA m^{-3}): 18–80	The highest concentrations of <i>Aspergillus</i> section <i>Fumigati</i> could be seen in seasons with less relative humidity and with stronger winds.	Priyamvada <i>et al.</i> (2017)

<i>Environmental Isolates of Multi-Azole-Resistant Aspergillus spp. in Southern Italy</i>	Italy	8 Farms	Increase awareness of <i>Aspergillus</i> environmental mutations	Collection of soil, fruit, vegetable and cereal samples	Culture-based methods, PCR, azole-resistance test	<i>Aspergillus</i> section <i>Fumigati</i> : 0–2.36% <i>A. fumigatus</i> sensu stricto: 0%–2.36%	There was a high prevalence of phenotypic resistance in <i>Aspergillus</i> not belonging to the <i>Fumigati</i> section, indicating that other species considered common may be present in the environment with assigned resistance.	Trovato et al. (2018)
<i>Airborne Aspergillus fumigatus</i> contamination in an intensive care unit: Detection, management and control	Belgic	1 Secondary care hospital	Description of an outbreak of <i>Aspergillus fumigatus</i>	Surface swab, impaction air sampling	Culture-based methods, MALDI-TOF	Surface swab: 1.0×10^1 CFU cm ⁻² – 1.0×10^1 CFU cm ⁻² <i>Aspergillus</i> section <i>Fumigati</i> : 0 CFU cm ⁻² Air sampling: 1 CFU cm ⁻³ – 6.4×10^2 CFU cm ⁻³ <i>Aspergillus</i> section <i>Fumigati</i> : $> 1 \times 10^1$ CFU m ⁻³	There is a correlation between the number of conidia in the air and the number of cases of invasive aspergillosis. <i>A. fumigatus</i> was cultivated from different air samples. In this perspective, dust containing <i>Aspergillus</i> spores is difficult to avoid in an indoor setting, therefore air sampling must be done regularly in order to control this risk factor.	Demuyser et al. (2019)
<i>Environmental Hotspots for Azole Resistance Selection of Aspergillus fumigatus, the Netherlands</i>	Holland	5 Contamination Hotspots	Find possible sources of multi-resistant <i>A. fumigatus</i>	Collection of household and agricultural waste	Culture-based methods, PCR	<i>Aspergillus</i> section <i>Fumigati</i> : 1.5×10^3 CFU m ⁻³ – 2.3×10^5 CFU m ⁻³	The risk of developing resistance is considered low in composting environments, even with the presence of azoles. The risk of developing resistance varies according to local conditions, so it is important to maintain a conscious use of fungicides.	Schoustra et al. (2019)
<i>Towards a risk evaluation of workers' exposure to airborne and handborne microbial species as exemplified with waste collection workers</i>	Denmark	8 Trucks and 16 Waste collecting workers	Assess and support the possibility to perform a risk assessment based on bioaerosol exposure	Surface swab, air sampling by filtration	Culture-based methods, MALDI-TOF	Air sampling: 1.2×10^3 CFU m ³ – 1.8×10^5 CFU m ³ <i>Aspergillus</i> section <i>Fumigati</i> : 6.7×10^4 CFU m ³	Waste collection workers are exposed to a vast number of microbial species. 37 species of fungi were identified, making the risk evaluation hard based on so many species, although it is possible to some degree to evaluate the workers' exposure based on species identification. <i>A. Fumigatus</i> , <i>A. niger</i> and <i>P. italicum</i> shown to be highly inflammogenic species.	Madsen et al. (2020)

^aArticle that only assess prevalence.

of PCR for detection in 7 of the 24 studies (Chang *et al.*, 2013; Madsen *et al.*, 2015; Carvalho *et al.*, 2016; Viegas *et al.*, 2016a; Priyamvada *et al.*, 2017; Trovato *et al.*, 2018; Schoustra *et al.*, 2019).

The range of results varied from Below Detection to 9×10^6 CFU m⁻³ for air sampling (Timm *et al.*, 2009; Madsen *et al.*, 2015), 100 to 4.5×10^6 CFU g⁻¹ for bulk sampling (Madsen *et al.*, 2012; Queiroz *et al.*, 2013) and Below Detection to 1.8×10^5 CFU cm⁻² for surface sampling (Viegas *et al.*, 2016a) (Table 2).

Discussion

As mentioned, in order to perform a microbiological assessment, two kinds of sampling methods can be employed, the active and passive. The use of these methods has certain advantages and disadvantages. Regarding active methods they can obtain direct estimates of the number of culturable microorganisms in a given sample (Zollinger *et al.*, 2006; Viegas *et al.*, 2015). The volumes and times of sampling can be established and thus provide a more accurate estimate (Zollinger *et al.*, 2006; Viegas *et al.*, 2015). Some active sampling methods also allow for sample dilution which can be an asset in more contaminated environments (Thorne and Heederik, 1999; Viegas *et al.*, 2015). However, if the fungi present are in small numbers they may be misrepresented (Macher, 2001), due to risk of dehydration of microorganisms with the use of some of the active methods (De Nuntiis *et al.*, 2003).

Passive methods are considered necessary to ensure the bioburden assessment (Hayleeyesus and Manaye, 2014; Viegas *et al.*, 2020), to complement the microbiological characterization of the environment disclosing the identification of contamination sources and the assessment of the efficacy of cleaning procedures (Klánová and Hollerová, 2003; Stetzenbach *et al.*, 2004; Viegas *et al.*, 2016b, 2019). When compared with active methods, the passive methods show an advantage in the number of fungal species detected and counts, since they can collect contamination for longer periods (Viegas *et al.*, 2015, 2017), making this kind of sampling procedures an important complementary method to the active approach (Viegas *et al.*, 2016c, 2019). Thus, the usage of passive and active methods coupled together allow a better understanding of the contamination present and an improved characterization of indoor environments (Viegas *et al.*, 2014, 2016b; Caetano *et al.*, 2017; Viegas *et al.*, 2019, 2020). Indeed, active methods provide information about load and the passive methods allow to obtain a detailed information about contamination increasing the accuracy of the exposure assessment and consequently the risk characterization (Viegas *et al.*, 2017).

Regarding the assays to be applied, molecular tools show more reliable results, not only because of their limit of quantification allowing to detect lower values of conidia in the environment (McDevitt *et al.*, 2004), but also, in cases where there are species with very high prevalence's in the environment. Indeed, this situation can lead to the misidentification of species or even the non-identification of less prevalent species (Elliott *et al.*, 2000; Levine and Manders, 2004; Stoodley *et al.*, 2011; Jacovides *et al.*, 2012; Rudkjøbing *et al.*, 2016). The use of these methods, such as PCR provide accurate results achieving sensitivities of 79% and specificities of 94% (Tuon, 2007; Sun *et al.*, 2011; Avni *et al.*, 2012). Additionally, also provide a mean to analyze environmental air samples, allowing to correlate exposure to airborne fungi and the possible adverse health effects (McDevitt *et al.*, 2004). Although these methods present reliable results, they also have some limitations, such as, the requirement of expensive equipment, the possibility of the occurrence of false negatives due to the presence of inhibitors that may be present in the chemical composition of microorganisms or false positives due to the presence of DNA in the environment or in the laboratory (Lauri and Mariani, 2009). An important drawback in occupational exposure assessments is the fact that the molecular tools make no distinction between viable and non-viable microorganisms (Lauri and Mariani, 2009; Pritt, 2015; Madsen *et al.*, 2020).

Culture-based methods, on the other hand are reported to be less sensitive and require a higher time to achieve results than molecular methods (Hope *et al.*, 2005), although they present lower costs and allow the identification and analysis of resistances present in a given sample, making it a good tool for resistance surveillance of *Aspergillus fumigatus* (Montesinos *et al.*, 2017). Culture based-methods are also a reliable tool that allows to assess viable microorganisms in a given environment (Madsen *et al.*, 2020), this being an important factor to take in consideration in an occupational environment due to the higher ability to grow or reproduce that may represent an infectious potential for humans (Altug *et al.*, 2009). Indeed, the cell being viable causes production of gliotoxin, thus enhancing its cytotoxicity (Nouri *et al.*, 2015).

Conclusion

This study brings evidence that in order to have an accurate and reliable *Aspergillus* section *Fumigati* risk characterization, the combined use of active and passive sampling and the analysis of viable and non-viable components are needed.

Introduction

Fungi are responsible for skin diseases, infections of lung and other organs and bloodstream infections due to its presence in several environments (CDC, 2020b). These environments, where fungi can be present, include clinical sites, agriculture fields, food and feed industries, among others, as well as household environments (Hicks *et al.*, 2005; Park *et al.*, 2010; Cabo Verde *et al.*, 2015).

The fungi most commonly reported by the Centers for Disease Control and Prevention (CDC) are *Aspergillus* sp., *Blastomyces* sp., *Candida* sp., *Coccidioides* sp., *Cryptococcus* sp., *Histoplasma* sp., *Paracoccidioides* spp., *Pneumocystis jirovecii*, *Talaromyces* sp., *Sporothrix* sp. (CDC, 2020b). These fungi are responsible for diseases such as Aspergillosis, Blastomycosis, Candidiasis, Coccidioidomycosis, Cryptococcosis, Histoplasmosis, Pneumocystis and other diseases (NIAID, 2018). Some of these fungi, namely, *Aspergillus*, *Penicillium*, *Alternaria*, *Fusarium*, and *Claviceps*, among others, can produce mycotoxins, representing an additional concern for public health (Viegas *et al.*, 2018c).

Although potentially all populations are exposed to fungi, since they are ubiquitous (i.e., present in all environments), fungi can easily cause infections on specific population groups such as elderly, immunocompromised patients and children (Silva, 2010; Jain *et al.*, 2010; Aguiar *et al.*, 2014).

A more recent concern for the public health is the development of fungal resistance to drugs. Such ability is related to the capacity of adaptation of fungi when exposed to drugs (Jensen, 2016). Antimicrobial resistance has been described as product of healthcare practices and their overuse (WHO, 2020). However, antifungals have also been overused in agricultural environments due to the growing need for quality and productivity improvements in food production (Brauer *et al.*, 2019). The use of fungicides in agriculture is also related to climate change and its influence on the distribution of fungi (Viegas *et al.*, 2016). A vast group of drugs used to inhibit fungal growth are azoles. Azoles are molecules that present an azole ring that interferes with biosynthesis of ergosterol (a component of fungal cell membrane), causing its death (Sheehan *et al.*, 1999).

Fungal resistance to azoles has been described as a result of mutations in the genome. Most of these genomic changes are related to inhibition of lanosterol 14 α -demethylase enzyme, conferring fungal resistance to drugs that act at the level of ergosterol synthesis of the fungal cell membrane (Marichal *et al.*, 1999; Marie and White, 2009). These mutations in the fungal genome represent a major concern for the management of fungal infections in patients, which can affect various parts of the body. Failure on the treatment of these patients due to fungal resistance can lead to chronic health problems, and even death (CDC, 2020a).

The aim of this review article is to assess methodologies for fungi sampling and screening of azole resistance in environmental samples, as well as to describe the most reported resistant fungi in these environments. This work is important to evaluate the next steps on azole screening, for the development and future application of effective control measures.

Materials and Methods

This study reports the search of available data published between January 1, 2000 and January 31, 2020. The initial search terms were developed to identify studies on the fungal resistance to azoles in different environmental samples. The databases chosen were PubMed, Scopus, and Web of Science (WoS). Searches were carried out in English. The Search terms via PubMed were “fungal resistance in environmental samples” This search strategy led to 71 papers in all databases. Articles that did not meet the inclusion criteria and duplicates were excluded from further analysis (Table 1).

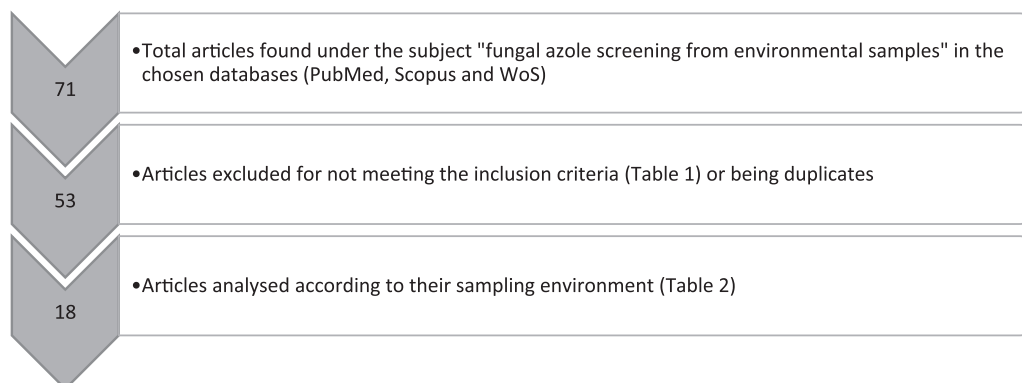

The diagram describes the different phases of the selection of papers (Fig. 1).

Results

Soil sampling was the most described (14 out of 18 studies) sampling method for the screening of azole resistance in environmental samples (Mortensen *et al.*, 2010; Chowdhary *et al.*, 2012; Yang *et al.*, 2012; Astvad *et al.*, 2014; Sharma *et al.*, 2015; Bader

Table 1 Inclusion and exclusion criteria in the articles selected

Inclusion criteria	Exclusion Criteria
Articles in English language	Articles in other languages
Articles published from January 1, 2000 to January 31, 2020	Articles published prior to 2000
Articles related to azole resistance	Articles related to biological samples
Articles related to environmental samples	Articles related to clinical and hospital samples
Scientific original articles on the topic/Journal Articles	Congress abstracts, Reviews, Reports
Identification of fungi to the genera level (at least).	
Articles related to Humans	Articles related to other species

**Fig. 1** Phases of the selection of articles.

et al., 2015; Toyotome *et al.*, 2016; Chowdhary *et al.*, 2016; Tangwattanachuleeporn *et al.*, 2017; Santoro *et al.*, 2017; Homa *et al.*, 2018; Vaezi *et al.*, 2018; Alvarez-Moreno *et al.*, 2019; Chen *et al.*, 2020). Air sampling was performed with two technique in three out of the 18 analyzed studies (Table 2): two by active air sampling with impaction method (Bromley *et al.*, 2014; Wang *et al.*, 2018) and one by collecting air conditioning filters (Viegas *et al.*, 2018a,b,c). In the studies of Bromley and Wang, soil samples were also collected as complementary method (Bromley *et al.*, 2014; Wang *et al.*, 2018). Water sampling was mentioned in one article only (Milanezi *et al.*, 2019).

The screening of azole resistance was performed using four methods, as follows: CLSI M38-A2 broth microdilution in 7 studies (Chowdhary *et al.*, 2012; Yang *et al.*, 2012; Toyotome *et al.*, 2016; Chowdhary *et al.*, 2014a,b; Homa *et al.*, 2018; Vaezi *et al.*, 2018; Milanezi *et al.*, 2019); EUCAST microdilution method in 9 studies (Mortensen *et al.*, 2010; Astvad *et al.*, 2014; Bromley *et al.*, 2014; Bader *et al.*, 2015; Sharma *et al.*, 2015; Tangwattanachuleeporn *et al.*, 2017; Wang *et al.*, 2018; Alvarez-Moreno *et al.*, 2019; Chen *et al.*, 2020); DMI sensitivity test in one study (Santoro *et al.*, 2017); and screening azole on supplemented media in another study (Viegas *et al.*, 2018a,b,c). CLSI M38-A2 broth and EUCAST microdilution reference methods were the most described (16 out of 18 studies).

Among the analyzed studies there were different fungal species tested for azole resistance: *Aspergillus* sp. (2 out of 18) (Bromley *et al.*, 2014; Viegas *et al.*, 2018a,b,c), *Aspergillus fumigatus* (13 out of 18) (Mortensen *et al.*, 2010; Chowdhary *et al.*, 2012, 2014a,b; Astvad *et al.*, 2014; Sharma *et al.*, 2015; Bader *et al.*, 2015; Toyotome *et al.*, 2016; Tangwattanachuleeporn *et al.*, 2017; Santoro *et al.*, 2017; Vaezi *et al.*, 2018; Wang *et al.*, 2018; Alvarez-Moreno *et al.*, 2019; Chen *et al.*, 2020), *Aspergillus* section *Nigri* and *Aspergillus* section *Candidi* (1 out of 18) (Viegas *et al.*, 2018a,b,c), *Candida* spp. (1 out of 18) (Milanezi *et al.*, 2019), *Candida tropicalis* (1 out of 18) (Yang *et al.*, 2012) and *Fusarium solani* (1 out of 18) (Homa *et al.*, 2018).

Only in two studies, assessing soil samples, azole resistance was not detected (Astvad *et al.*, 2014; Toyotome *et al.*, 2016). Azole resistance was detected in most studies (16 out of 18) (Mortensen *et al.*, 2010; Chowdhary *et al.*, 2012; Yang *et al.*, 2012; Chowdhary *et al.*, 2014a,b; Bromley *et al.*, 2014; Sharma *et al.*, 2015; Bader *et al.*, 2015; Tangwattanachuleeporn *et al.*, 2017; Santoro *et al.*, 2017; Homa *et al.*, 2018; Vaezi *et al.*, 2018; Wang *et al.*, 2018; Viegas *et al.*, 2018a,b,c; Milanezi *et al.*, 2019; Alvarez-Moreno *et al.*, 2019; Chen *et al.*, 2020). Among these, it was explored in two studies that azole resistance was led by mutations (Chowdhary *et al.*, 2012; Chen *et al.*, 2020).

Fungal resistance to itraconazole was described in 13 studies (Mortensen *et al.*, 2010; Chowdhary *et al.*, 2012, 2014a,b; Bromley *et al.*, 2014; Sharma *et al.*, 2015; Bader *et al.*, 2015; Tangwattanachuleeporn *et al.*, 2017; Viegas *et al.*, 2018a,b,c; Vaezi *et al.*, 2018; Wang *et al.*, 2018; Homa *et al.*, 2018; Alvarez-Moreno *et al.*, 2019; Chen *et al.*, 2020). Fungal resistance to voriconazole was described in 13 studies (Mortensen *et al.*, 2010; Chowdhary *et al.*, 2012, 2014a,b; Bromley *et al.*, 2014; Sharma *et al.*, 2015; Bader *et al.*, 2015; Tangwattanachuleeporn *et al.*, 2017; Santoro *et al.*, 2017; Homa *et al.*, 2018; Vaezi *et al.*, 2018; Wang *et al.*, 2018; Viegas

Table 2 Data obtained from the chosen articles

Database	Title	Country	Environment/samples description	Sampling methods	Azole resistance analyses methods	Main findings	References
PubMed	<i>Azole susceptibility in clinical and environmental isolates of Aspergillus fumigatus from Eastern Hokkaido, Japan</i>	Japan	Soil samples from Tokachi area of Eastern Hokkaido	Soil samples	CLSI M38-A2 broth microdilution	From the 91 isolates were susceptible to medical azole. It suggests that TR34/L98H- or TR46/Y121F/T289A-type are not prevalent in the samples area.	Toyotome et al. (2016)
	<i>Multi-azole-resistant Aspergillus fumigatus in the environment in Tanzania</i>	Tanzania	Soil and woody debris samples from the surroundings of Kilimanjaro Christian Medical Center, Tanzania	Soil samples	CLSI M38-A2 broth microdilution	Out of the 108 isolates, 4 were found voriconazole resistance and 11 voriconazole and itraconazole resistant. All isolates were also resistant to the 10 azole fungicides tested.	Chowdhary et al. (2014a,b)
	<i>First Detection of TR46/Y121F/T289A and TR34/L98H Alterations in Aspergillus fumigatus Isolates from Azole-Naive Patients in Denmark despite Negative Findings in the Environment</i>	Denmark	Soil samples were collected from indoor flowerpots of a university hospital in Copenhagen, from an amusement park in the center of Copenhagen, conventionally grown fields and organic grown fields.	Soil samples	EUCAST method	The azole resistance was not detected in any of the soil samples.	Astvad et al. (2014)
	<i>Aspergillus prevalence in air conditioning filters from vehicles: Taxis for patient transportation, forklifts, and personal vehicles</i>	Portugal	Air conditioning filters from vehicles: 19 samples from taxis, 17 samples from forklifts and 37 samples from personal vehicles	Air conditioning filters sampling	Screening in azole-supplemented media	In forklifts filters, <i>Aspergillus</i> section <i>Nigri</i> was the most prevalent species grown in azole-supplemented media being 76% in 4 mg/L of itraconazole, 43% in 1 mg/L of voriconazole and 0,33% in 0,05 mg/L of posaconazole; In taxis filters, it was only found <i>Aspergillus</i> section <i>Candidi</i> identified in 4 mg/L of itraconazole. In filters from personal vehicles no <i>Aspergillus</i> species were detected.	Viegas et al. (2018a,b,c)
Scopus	<i>Comparison of Human and Soil Candida tropicalis Isolates with Reduced Susceptibility to Fluconazole</i>	China	Soil samples from agriculture fields; petroleum contained soil; sludge soil and agricultural fields	Soil samples	CLSI M38-A2 broth microdilution	From 11 soil <i>C. tropicalis</i> isolates, 6 were less susceptibility to fluconazole. Soil could be a source of <i>C. tropicalis</i> with reduced susceptibility to azole type of antifungal drugs.	Yang et al. (2012)

Web of Science	<i>Occurrence of azole-resistant species of Aspergillus in the UK environment</i>	United Kingdom	Air sampling and soil sampling	Air sampling collected by impaction method; Soil samples	EUCAST method	Azole resistance was only detected in field isolates. These results support the hypothesis that the use of azoles in agriculture may lead to environmental fungi resistance of clinical importance.	Bromley et al. (2014)
	<i>Antifungal susceptibility of yeasts isolated from anthropogenic watershed</i>	Brazil	Water samples collected along Guaíba lake course.	Water samples	CLSI M38-A2 broth microdilution	From the 95 isolates, 16.8% were resistant to Amphotericin B. It was possible to identify among the isolates, <i>Candida</i> spp. and <i>Debaryomyces</i> spp.	Milanezi et al. (2019)
	<i>High Azole Resistance in Aspergillus fumigatus Isolates from Strawberry Fields, China, 2018</i>	China	Soil samples from agricultural farms or greenhouses located in 8 cities of China.	Soil core samples	EUCAST method	From 63 soil samples, of 206 <i>A. fumigatus</i> isolates, 21 (10.2%) were triazole resistance. Nineteen out of these 21 isolates had mutation on cyp51A gene.	Chen et al. (2020)
	<i>Triazole-resistant Aspergillus fumigatus harboring G54 mutation: Is it de novo or environmentally acquired?</i>	India, Romania, Tanzania	Soil and woody debris samples from flowerbeds, parks of hospitals, agricultural fields from Moshi, Tanzania.	Soil and woody debris samples	EUCAST method	From a total of 81 samples, was detected triazole-resistant <i>A. fumigatus</i> in 25% of the samples (20/81). In 16 out of these this 20 samples, a resistance mechanism was detected, associated with a mutation.	Sharma et al. (2015)
	<i>Clonal Expansion and Emergence of Environmental Multiple-Triazole-Resistant Aspergillus fumigatus Strains Carrying the TR34/L98H Mutations in the cyp51A Gene in India</i>	India	Soil samples collected from flowerbeds of nurseries, hospital parks, cotton trees, tea gardens, soil containing bird excreta, decayed wood of tree trunks from different regions of India.	Soil samples	CLSI M38-A2 broth microdilution	The results suggest that exposure to <i>A. Fumigatus</i> to azole fungicides in the environment causes cross-resistance to medical triazole.	Chowdhary et al. (2012)
	<i>Fungicide-driven alterations in azole-resistant Aspergillus fumigatus are related to vegetable crops in Colombia, South America</i>	Colombia	Soil samples from several crops (potatoes, maize, carrots, strawberries, peas, and soil ready to be planted).	Soil samples	EUCAST method	15 samples of <i>A. fumigatus</i> grew on agar supplemented with ITZ and VOR. The study evidence the dissemination of azole-resistant <i>A. Fumigatus</i> , with high genetic diversity in vegetable crops in Colombia	Alvarez-Moreno et al. (2019)

Table 2 Continued

Database	Title	Country	Environment/samples description	Sampling methods	Azole resistance analyses methods	Main findings	References
	<i>South Indian Isolates of the Fusarium solani Species Complex from Clinical and Environmental Samples: Identification, Antifungal Susceptibilities, and Virulence</i>	India	Soil and plant parts samples from gardens, parks, yards and agricultural fields in the surroundings of Coimbatore.	Soil samples	CLSI M38-A2 broth microdilution	The first generation triazoles, fluconazole and itraconazole, as expected, were not effective against all isolates tested. The results also lead to the conclusion that the intensive agriculture use of azole compounds, the fusaria has not developed resistance against the imidazole class of antifungals.	Homa et al. (2018)
	<i>Pesticide behavior in paddy fields and development of azole-resistant Aspergillus fumigatus: Should we be concerned?</i>	Iran	Soil samples from rice farms around Mazandaran	Soil samples	CLSI M38-A2 broth microdilution	From the results, 31 of the 108 isolates were identified as <i>A. fumigatus</i> and 4 were recognized as azole-resistant for itraconazole and voriconazole. The study recognized the pesticides behavior, as tricyclazole in the rice paddy fields, having an effective role in the development of azole-resistance that requires detailed information.	Vaezi et al. (2018)
	<i>Prevalence, mechanisms and genetic relatedness of the human pathogenic fungus Aspergillus fumigatus exhibiting resistance to medical azoles in the environment of Taiwan</i>	Taiwan	Air samples and soil samples from hospitals, communities, and farmlands	Air samples collected by impaction method; Soil samples	EUCAST method	From 29 samples, 34 isolates displayed resistance to itraconazole, voriconazole and posaconazole. The results emphasize the need of surveillance where azole fungicides are applied.	Wang et al. (2018)
	<i>Environmental Study of Azole-Resistant Aspergillus fumigatus and Other Aspergilli in Austria, Denmark, and Spain</i>	Austria, Denmark, and Spain	Soil samples from park in the center of Copenhagen, compost bags from Denmark, Austria and Spain	Soil samples	EUCAST method	From the Danish soil samples, 4 <i>A. fumigatus</i> isolates displayed high azole resistance. One <i>A. Lentulus</i> isolate with voriconazole resistance was detected in Spain.	Mortensen et al. (2010)
	<i>Prevalence of azole-resistant Aspergillus fumigatus in the environment of Thailand</i>	Thailand	Soil samples from urban and agriculture sites across Thailand	Soil samples	EUCAST method	All the isolates were resistant to itraconazole, 2 showed additional resistance to posaconazole and one other to voriconazole.	Tangwattanachuleeporn et al. (2017)

<i>Environmental Isolates of Azole-Resistant Aspergillus fumigatus in Germany</i>	Germany	Soil samples from environment	Soil samples	EUCAST method	All the isolates showed resistance to at least one of the antifungals. The resentence results agree with applied molecular tools.	Bader et al. (2015)
<i>Abundance, genetic diversity and sensitivity to demethylation inhibitor fungicides of Aspergillus fumigatus isolates from organic substrates with special emphasis on compost</i>	Italy, Spain, and Hungary	56 soil samples from meadow/forest	Soil samples	DMI sensitivity testing	It was used 4 DMI fungicides such as: epoxiconazole, difenoconazole, imazilil and posaconazole being imazilil the one with the most antifungal activity followed by posaconazole; Difenonconazole was about 5–7 times less active and epoxiconazole 15–24 times; 3 resistant isolates were tested also for voriconazole e itraconazole being 100-fold less active compared to posaconazole	Santoro et al. (2017)

et al., 2018a,b,c; Alvarez-Moreno *et al.*, 2019; Chen *et al.*, 2020). Fungal resistance to posaconazole was described in 11 studies (Mortensen *et al.*, 2010; Chowdhary *et al.*, 2012; Bromley *et al.*, 2014; Bader *et al.*, 2015; Sharma *et al.*, 2015; Santoro *et al.*, 2017; Tangwattanachuleeporn *et al.*, 2017; Homa *et al.*, 2018; Wang *et al.*, 2018; Viegas *et al.*, 2018a,b,c; Chen *et al.*, 2020). Eight studies also described resistance to other antifungal drugs, non-azoles, such as Amphotericin B (Mortensen *et al.*, 2010; Yang *et al.*, 2012; Chowdhary *et al.*, 2014a,b; Bader *et al.*, 2015; Santoro *et al.*, 2017; Homa *et al.*, 2018; Vaezi *et al.*, 2018; Milanezi *et al.*, 2019).

Discussion

This review focus on azole resistance screening in environmental samples. Regarding sampling methodology, the collection of air, water, and soil samples was described in the analyzed studies. Air sampling was performed using the impactor method, which was proven to be the most efficient for fungal assessment in the environment, including in clinical environments (Nesa *et al.*, 2001). The soil sampling appears to be commonly used as a single method for environmental sampling (Toyotome *et al.*, 2016; Chowdhary *et al.*, 2014a,b; Astvad *et al.*, 2014; Yang *et al.*, 2012; Chen *et al.*, 2020; Sharma *et al.*, 2015; Chowdhary *et al.*, 2012; Alvarez-Moreno *et al.*, 2019; Homa *et al.*, 2018; Vaezi *et al.*, 2018; Mortensen *et al.*, 2010; Tangwattanachuleeporn *et al.*, 2017; Bader *et al.*, 2015; Santoro *et al.*, 2017).

In fact, in outdoor environments the fungal load present in the air can be very high (Uddin and Chakraverty, 1994; Shelton *et al.*, 2020). This might explain why some studies only used soil sampling: using the impactor method would request the lowering of the air liters pumped into the plates so they would not be overgrowth. By doing so, the samples collected could not be representative of the microbial load present in these outdoor environments (Yao and Mainelis, 2007). It is important, however, to assess the fungi present in the air in outdoor environments. Impinger methods, due to the use of liquid samples, allow obtaining dilutions to avoid countless growth in media plates, while allowing the use of molecular tools for both fungal molecular detection and further genome sequencing (Viegas *et al.*, 2015, 2018a,b,c).

Regarding the analyzed environments, most of them are related to outdoor environments such as agricultural fields or surrounding parks of hospitals, including flowerbeds and forest/meadow. The similarities between azoles used in the clinical practice and agricultural fungicides present in these environments show a link between fungal resistance and the development of resistance of human fungal pathogens caused by azole pressure in the environment and in clinical practice, increasing public health concerns (Hollomon, 2017).

Studies have shown that vehicle filters also represent a source of fungal contamination (Aquino *et al.*, 2018; Simmons *et al.*, 1997). Fungal contamination of air conditioning filters, either in vehicles or in buildings and resultant health effects represent a matter of concern for both public health and occupational health. While microbial identification (besides bacterial and fungal counts) is important for a more accurate risk characterization, additional assessment of fungal resistance to azoles is important for a better characterization of exposure and health risks in these environments (Viegas *et al.*, 2018a,b,c). For this sampling, the analysis of air conditioning filters turn out to be very efficient, since it is possible to dilute the samples and use molecular methods for fungal quantification and identification, complementary to culture-based methods (Viegas *et al.*, 2015, 2018a,b,c).

An important aspect for fungal proliferation is climate change and anthropogenic actions, which contribute to events such as floods (NCA, 2020). These occurrences help in the spread and transmission of fungi and can be present in wells, puddles or even lakes, also representing a very important environment to be analyzed (OSHA, 2020; Milanezi *et al.*, 2019).

Most of the studies search for azole resistance in fungi with some clinical significance for human health, such as *Aspergillus* spp., *Aspergillus fumigatus*, *Aspergillus* section *Nidulantes*, *Aspergillus* section *Nigri*, *Aspergillus* section *Candidi*, *Candida tropicalis*, *Fusarium solani*, *Penicillium* sp.

Aspergillus spp. was described in many environments and reported worldwide (Gaffi, 2020). The consequences of aspergillosis are very well described not only as allergenic reactions but also other chronic diseases in lungs (Richardson and Rautemaa-Richardson, 2019). The health concern about these genera is exacerbated by the toxigenic species such *Aspergillus flavus* and *Aspergillus fumigatus* (Viegas *et al.*, 2020). *Aspergillus fumigatus* is the most studied *Aspergillus* species for its resistance against the three most used azoles in patient's treatment: itraconazole, voriconazole and posaconazole, specially, in patients with lung diseases (Hamprecht *et al.*, 2018; Morio *et al.*, 2017). Fungal resistance to azoles was also described for *Aspergillus fumigatus* in agricultural samples (Berger *et al.*, 2017). *Aspergillus* spp. and consequent aspergillosis happens to be the larger cause of death by fungal disease (Latgé, 1999).

Candida spp. appears to also be a very well reported genera for multiple health problems such as bloodstream infections. The *Candida* resistance against fluconazole represents a public health concern (Ben-Ami *et al.*, 2012). All the other studied genera (*Fusarium solani*, *Penicillium* sp.) are related with respiratory tract infections with high reported resistance to azoles (Chowdhary *et al.*, 2016).

According to the sampling methods used to test the susceptibility of fungi to azoles, the methods commonly used are EUCAST (Tudela *et al.*, 2008; Arendrup *et al.*, 2012) and CLSI M38–A2 broth microdilution (Treviño-Rangel and González, 2015; Espinel-Ingroff and Canton, 2008). In these methods, the azoles frequently used to test fungi susceptibility are itraconazole, voriconazole and posaconazole (Chowdhary *et al.*, 2014a,b; Viegas *et al.*, 2018a,b,c) being these azoles used as the first-line treatments in aspergillosis therapy (Mroczynska *et al.*, 2020; Rudramurthy *et al.*, 2016) and molecularly similar to the azole fungicides used in agricultural practices, for instance, in crop protection (Bowyer and Denning, 2013; Santoro *et al.*, 2017).

Some studies describe a correlation between the resistance of *Aspergillus* spp. to azoles and a mutation in the *cyp51A* gene, which increases the number of aspergillosis infections (Rajendran *et al.*, 2016).

In conclusion, the biggest challenge is to ensure a global surveillance of azole resistance in all the environments, in order to establish an accurate scenario of exposure risk both in the clinic and in the environment. Therefore, more studies in different environments, especially in occupational environments, on sampling and azole resistance testing, are necessary to achieve this goal. Besides broadening sampling methodologies, it is also recommended to use complementary methods for fungal characterization so that it can better describe what exists in these environments. In relation to the studies performed, especially in agricultural environments, it is important to evaluate fungal resistance in more environments to better characterize the fungi present and their resistance to azoles.

Introduction

Fungal infections are emerging as an important cause of human disease around the globe (Bongomin *et al.*, 2017). Fungal infections include superficial mycoses, such as pityriasis versicolor, and systemic mycoses, such as aspergillosis. Systemic invasive fungal infections are commonly related to situations where patients are immunocompromised, such as cancer and AIDS patients, during corticosteroid therapies and others (Bongomin *et al.*, 2017; Enoch *et al.*, 2016).

Among the most commonly used antifungal drugs are amphotericin B, 5-flucytosine and azoles (Willey *et al.*, 2008). Azoles are a group of antifungal agents with broad spectrum of activity. They are divided in two main groups, according to the base molecule: imidazole based azoles, such as clotrimazole, ketoconazole, miconazole, and triazole derivatives, such as itraconazole, voriconazole, and posaconazole. Their mechanism of action is focused on the inhibition of the fungal cytochrome P450 3A enzyme, lanosterol 14- α -demethylase, blocking the conversion of lanosterol into ergosterol, resulting in a depletion of this compound, which alters the fluidity of the fungal membrane (Rang *et al.*, 2016).

During recent years there has been an increase of resistance to the available antifungal agents, becoming a significant public health concern especially among individuals at higher risk of opportunistic fungal infections such as immunocompromised individuals (Barker and Rogers, 2006; Wiederhold, 2017). Azole resistance may develop in consequence of fungal exposure to azole compounds, which may occur during a patient's treatment with these antifungal drugs or through the use of azole fungicides similar to clinical azole drugs, such as in agriculture (Snelders *et al.*, 2008). Among acquired antifungal resistance, the azole resistance has been noticeable increasing, being found in isolates of *Candida* and *Aspergillus*, mostly *A. section Fumigati* (Wiederhold, 2017).

Healthcare facilities must provide a controlled environment in order to guarantee the security of patients and avoid the dissemination of potentially pathogenic airborne contaminants. Thus, indoor air quality must be regularly monitored and controlled in healthcare facilities, and must also include a rigorous biological assessment, in order to be able to characterize the risk of contamination by pathogenic microorganisms for patients, staff, and visitors (Qudiesat *et al.*, 2009).

The present study aims to perform a scope review of the assessments of fungal resistance to azole drugs performed on healthcare facilities' indoor environments in the last decade and to suggest a methodological approach for the screening of fungal resistance in those environments.

Materials and methods

In this study, available data on azole resistance in healthcare facilities' indoor environments, including hospitals and primary healthcare centers, published between January 1, 2000 and October 31, 2019 was searched, following the PRISMA methodology. The initial search terms were chosen to identify studies on the assessment of azole resistance in healthcare facilities' environments, focusing on fungal sampling and screening of azole resistance. The databases chosen were PubMed, Scopus, and Google Scholar. Searches were carried out in English. The Search terms were "Azole Resistance" and "Hospital Indoor Environments". This search strategy led to nearly 125 papers in all databases. Articles that did not meet the inclusion criteria and duplicates were excluded from further analysis (Table 1).

The diagram describes the different phases of the selection of papers (Fig. 1).

Results

A total of 12 articles were analyzed regarding the environmental setting (hospitals or other healthcare facilities), sampling methods, fungal identification methods, type of azole resistance identified (and the used methods, when possible), and the main conclusions of each study.

Most studies described the assessment of azole resistance in hospital environments (11 out of 12), the exception being one study performed in primary health care centers (Caetano *et al.*, 2019). Six studies mentioned indoor and outdoor sampling for comparison purposes (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Loeffert *et al.*, 2018; Chen *et al.*, 2019; Cho *et al.*, 2019; Monteiro *et al.*, 2019), and three studies compared the resistance phenotypes in environmental and clinical samples (Loeffert *et al.*, 2018; Chen *et al.*, 2019; Cho *et al.*, 2019).

Air sampling was the most frequent sampling method (10 out of 12 studies) (Panagopoulou *et al.*, 2007; Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Mohammadi *et al.*, 2016; San Juan *et al.*, 2017; Loeffert *et al.*, 2018; Chen *et al.*, 2019; Cho *et al.*, 2019;

Table 1 Inclusion and exclusion criteria in the articles selected

Inclusion Criteria	Exclusion Criteria
Articles published in the English language;	Articles published in other languages
Articles published from 2000 to present	Articles published prior to 2000
Articles published in any country	
Articles related to fungi assessment in healthcare institutions environments	Articles related exclusively to biologic samples from patients
Articles related to hospital environments including other healthcare facilities	Articles containing information exclusively from non-health related environments
Original scientific articles on the topic	Abstracts of congress, reports, reviews/ state of the art articles
Identification of fungi to the genera level (at least)	

**Fig. 1** PRISMA based selection of articles.

Monteiro *et al.*, 2019; Viegas *et al.*, 2019a). Air sampling was the only sampling method used in five studies (San Juan *et al.*, 2017; Loeffert *et al.*, 2018; Chen *et al.*, 2019; Cho *et al.*, 2019; Monteiro *et al.*, 2019), and used in parallel with passive sampling methods in other five studies (Panagopoulou *et al.*, 2007; Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Mohammadi *et al.*, 2016; Viegas *et al.*, 2019a).

Passive sampling methods used for the assessment of fungal contamination in the analyzed studies were water sampling (Panagopoulou *et al.*, 2007; Snelders *et al.*, 2009; Ahmad *et al.*, 2014), surface swabs (Panagopoulou *et al.*, 2007; Savastano *et al.*, 2016; Ahmad *et al.*, 2014; Mohammadi *et al.*, 2016; Viegas *et al.*, 2019a), soil sampling (Snelders *et al.*, 2009), settled dust (Caetano *et al.*, 2019; Viegas *et al.*, 2019a), electrostatic dust collector (EDC) (Caetano *et al.*, 2019; Viegas *et al.*, 2019a), HVAC filter sampling (Caetano *et al.*, 2019), and staff hands and lab coats (Savastano *et al.*, 2016).

Regarding methods of fungal identification, all studies performed morphological identification. One study on *Candida* sp. performed physiological tests additional to morphological identification (Savastano *et al.*, 2016). Eight studies used molecular detection of fungal DNA in parallel with morphological identification (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Mohammadi *et al.*, 2016; Loeffert *et al.*, 2018; Cho *et al.*, 2019; Chen *et al.*, 2019; Monteiro *et al.*, 2019; Viegas *et al.*, 2019a).

Most of the analyzed scientific articles (10 out of 12) explicitly included terminology related to “resistance” or “azole-resistance” (Snelders *et al.*, 2009; Caetano *et al.*, 2019; Ahmad *et al.*, 2014; Loeffert *et al.*, 2018; Chen *et al.*, 2019; Monteiro *et al.*, 2019) or “antifungal susceptibility” (Panagopoulou *et al.*, 2007; Mohammadi *et al.*, 2016; San Juan *et al.*, 2017; Cho *et al.*, 2019; Monteiro *et al.*, 2019) in the title, of which five specified *Aspergillus fumigatus* (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Mohammadi *et al.*, 2016; Loeffert *et al.*, 2018; Monteiro *et al.*, 2019) and three *Aspergillus* sp. (San Juan *et al.*, 2017; Chen *et al.*, 2019; Cho *et al.*, 2019).

Seven studies referred to CLSI protocols to determine azole-resistance (Panagopoulou *et al.*, 2007; Snelders *et al.*, 2009; Savastano *et al.*, 2016; Ahmad *et al.*, 2014; San Juan *et al.*, 2017; Chen *et al.*, 2019; Cho *et al.*, 2019), and five studies used the use of EUCAST guidelines (Caetano *et al.*, 2019; Mohammadi *et al.*, 2016; Loeffert *et al.*, 2018; Monteiro *et al.*, 2019; Viegas *et al.*, 2019a).

Aspergillus fumigatus was the most commonly described fungal species (7 out of 12 studies) (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Mohammadi *et al.*, 2016; Loeffert *et al.*, 2018; Chen *et al.*, 2019; Cho *et al.*, 2019; Monteiro *et al.*, 2019), with phenotype of azole resistance confirmed in five studies (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Chen *et al.*, 2019; Cho *et al.*, 2019; Monteiro *et al.*, 2019), and one study reporting all *Aspergillus fumigatus* isolates, although not azole-resistant, susceptible to voriconazole and itraconazole at very high MIC's (Loeffert *et al.*, 2018). Other *Aspergillus* sp., reported as azole-resistant or with reduced susceptibility to azoles at tested concentrations, were *A. niger* (San Juan *et al.*, 2017; Cho *et al.*, 2019), *A. flavus* (Cho *et al.*, 2019), *A. versicolor* (Viegas *et al.*, 2019a), and *Aspergillus* cryptic species (Monteiro *et al.*, 2019). Regarding the evaluation of azole resistance of other fungal species, two studies described the occurrence of filamentous fungi able to grow in triazoles in Primary Healthcare Centers (Caetano *et al.*, 2019) and in one central hospital (Viegas *et al.*, 2019a), and another study the occurrence of azole resistance among several non-*albicans* *Candida* species (Savastano *et al.*, 2016).

Itraconazole-resistance was the most common type of azole resistance (6 out of 12 studies) referent to *A.* section *Fumigati* (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Loeffert *et al.*, 2018; Monteiro *et al.*, 2019), *A.* section *Nigri* (San Juan *et al.*, 2017) and non-*Aspergillus* species (Caetano *et al.*, 2019), followed by multiazole-resistance (5 out of 12 studies) referent to *A.* section *Fumigati* (Chen *et al.*, 2019; Cho *et al.*, 2019; Monteiro *et al.*, 2019) and non-*Aspergillus* species (Savastano *et al.*, 2016; Viegas *et al.*, 2019a). Reduced susceptibility to voriconazole was mentioned in three studies referent to *A.* section *Fumigati* (Loeffert *et al.*, 2018), *A.* section *Versicolores* (Viegas *et al.*, 2019a) and non-*Aspergillus* species (Caetano *et al.*, 2019), whereas reduced susceptibility to posaconazole or other azole drugs were mentioned in four studies referent to *A.* section *Fumigati* (Monteiro *et al.*, 2019) and non-*Aspergillus* species (Caetano *et al.*, 2019; Savastano *et al.*, 2016; Viegas *et al.*, 2019a).

Of the six studies that used molecular methods, five targeted fungal DNA mutations related to azole-resistance, namely, mutations among the TR₃₄/L98H codon (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Mohammadi *et al.*, 2016; Chen *et al.*, 2019; Monteiro *et al.*, 2019). In four of these studies mutations associated with azole resistance were effectively detected and related either with itraconazole-resistance or with multiazole-resistance (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Cho *et al.*, 2019; Chen *et al.*, 2019). Among all articles that described azole resistance, only one study described azole resistance non-related to any CYP51A gene mutation (Monteiro *et al.*, 2019). The occurrence of mutations with no phenotype of azole-resistance was not reported in the analyzed studies (Table 2).

Discussion

Hospital-acquired infections represent an important issue of public health and are repeatedly the cause of morbidity and mortality for patients admitted to hospitals. The bioburden in the hospital environment is unsurprisingly vast and includes opportunistic pathogens that originate not only indoor from patients, relatives or healthcare practitioners, but also from outdoor environmental sources being disseminated indoor (Viegas *et al.*, 2019a). In particular, exposure to mycobiota in indoor environments has been related to several adverse human health effects (Douwes *et al.*, 2003; Alberti *et al.*, 2001). *Aspergillus* sp. and *Candida* sp. have been the most frequently isolated agents in clinical samples corresponding to a high burden of the hospital-acquired fungal infections with high mortality (Nicolle *et al.*, 2011; Snelders *et al.*, 2009; Cho *et al.*, 2019; Savastano *et al.*, 2016). Increasing research on mycology and fungal infections in past years has clarified the role of a growing number of fungal species in different health conditions such as *Fusarium* and *Penicillium* spp., or *Alternaria* and *Cladosporium* spp. (Chowdhary *et al.*, 2016), which are fungal species commonly found in indoor environments, namely, hospitals and healthcare facilities (Caetano *et al.*, 2019; Viegas *et al.*, 2019a).

The transmission occurs in different ways according to the microorganism involved. *Aspergillus* sp. are ubiquitous saprophytic fungi and their conidia easily inhaled, while person-to-person transmission is unlikely. *Candida* spp. infections are primarily of an endogenous origin, but transmission may also occur through hands of staff or visitors, or through hospital devices (Savastano *et al.*, 2016). Furthermore, the emergence of antifungal resistance is an important concern related to almost all main groups of pathogenic microorganisms, mostly described for *Aspergillus* section *Fumigati* (Snelders *et al.*, 2011; Verweij *et al.*, 2016; Fisher *et al.*, 2018) and non-*albicans* *Candida* species (Mar *et al.*, 2000; Savastano *et al.*, 2016). Azole resistance can develop by means of fungal exposure to azole compounds, which may occur in azole-treated patients or through the use of azole compounds in the

Table 2 Data obtained from the chosen articles

Database	Title	Country	Environment description	Sampling methods	Fungal identification	Azole resistance	Results	Conclusions	References
Google Scholar	Filamentous Fungi in a Tertiary Care Hospital Environmental Surveillance and Susceptibility to Antifungal Drugs	Greece	One hospital, indoor	Air sampling, water sampling, surface swabs	Morphological identification	CLSI reference method	All 54 <i>Aspergillus</i> air isolates exhibited relatively low minimum inhibitory or effective concentrations for amphotericin B, itraconazole, voriconazole, posaconazole, micafungin, and anidulafungin.	Air and surface fungal loads vary in different departments. Environmental <i>Aspergillus</i> isolates lacked resistance to clinically important antifungal agents.	Panagopoulou et al. (2007)
	Possible Environmental Origin of Resistance of <i>Aspergillus fumigatus</i> to Medical Triazoles	Netherlands and USA	One hospital, indoor and outdoor	Air and water sampling (culture collection), soil sampling	Morphological and molecular identification	CLSI reference method Microsatellite genotyping	Five out of 248 (2%) indoor and six out of 49 (12%) outdoor <i>A. fumigatus</i> isolates grew on itraconazole. TR/L98H mutation related to itraconazole resistance (86%) with environmental and clinical azole-resistant isolates clustering together.	Invasive aspergillosis due to azole-resistant <i>A. fumigatus</i> might be caused by the acquisition of the resistant fungi, present in the hospital environment.	Snelders et al. (2009)
	Assessment of Azole Resistance In Clinical Settings by Passive Sampling	Portugal	Ten Primary Healthcare Centers, indoor	EDC sampling, HVAC filter sampling, settled dust	Morphological identification	EUCAST reference method (adapted)	No <i>Aspergillus</i> sp. grew on azole-media. Other filamentous fungal species grew on itraconazole (n=9), voriconazole (n=6), and posaconazole (n=3) considering all sampling methods.	Passive sampling allows quantitative and qualitative characterization of fungal burden. EDC sampling provided the best characterization of fungal species diversity and should be included in the assessment of fungal resistance.	Caetano et al. (2019)
	<i>Candida glabrata</i> among <i>Candida</i> spp. from environmental health practitioners of a Brazilian Hospital	Brazil	One hospital, indoor	Surface swabs, hands and lab coats	Morphological identification and physiological tests	CLSI reference method	Resistant isolates of <i>C. albicans</i> were not found. All isolates of non- <i>albicans Candida</i> exhibited decreased susceptibility to miconazole and itraconazole, but susceptible to nistatin.	Surveillance programs are important to evaluate the trends of <i>Candida</i> species and their resistance profiles to antifungal drugs commonly used in medical practice.	Savastano et al. (2016)
PubMed	Occurrence of triazole-resistant <i>Aspergillus fumigatus</i> with TR34/L98H mutations in outdoor and hospital environment in Kuwait	Kuwait	One hospital, indoor and outdoor	Air and water sampling, surface swabs	Morphological and molecular identification	CLSI reference method	7% <i>A. fumigatus</i> isolates from indoor samples were resistant to itraconazole. TR ₃₄ /L98H mutation detected in all itraconazole-resistant isolates.	Triazole-resistant <i>A. fumigatus</i> with TR ₃₄ /L98H mutations in <i>cyp51A</i> is prevalent in Kuwait. The presence of triazole-resistant <i>A. fumigatus</i> in the hospital environment is a risk for susceptible patients.	Ahmad et al. (2014)

Determination of antifungal susceptibility patterns among the environmental isolates of <i>Aspergillus fumigatus</i> in Iran	Iran	Three hospitals, indoor	Air sampling, surface swabs	Morphological and molecular identification	<i>EUCAST reference method</i>	No azole-resistant isolates found among environmental isolates of <i>A. fumigatus</i> .	There were no azole-resistant fungi among environmental isolates obtained from these hospitals.	Mohammadi et al. (2016)
<i>In vitro</i> susceptibility of Cuban <i>Aspergillus</i> spp. strains of clinical and environmental origin	Cuba	Hospital, indoor	Air sampling	Morphological identification	<i>CLSI reference method, Etest™</i>	<i>A. niger</i> (5% of all isolates) was itraconazole-resistant.	Resistance to azoles presented low-frequency.	San Juan et al. (2017)
Prospective survey of azole drug resistance among environmental and clinical isolates of <i>Aspergillus fumigatus</i> in a French University hospital during major demolition works	France	One hospital – indoor and outdoor, and surveillance of invasive aspergillosis cases	Air sampling	Morphological and molecular identification	<i>EUCAST reference method (adapted)</i>	No <i>A. fumigatus</i> isolates were azole-resistant, although all exhibited susceptibility to voriconazole and itraconazole at very high MIC's.	Although no azole-resistant isolates were found, the presence of isolates susceptible to azoles at high MIC's alerts to the potential role of contaminated environments as sources of azole-resistant invasive aspergillosis	Loeffert et al. (2018)
Azole resistance in <i>Aspergillus</i> species in Southern Taiwan: an epidemiological surveillance study	Taiwan	One hospital, indoor and outdoor, <i>Aspergillus</i> clinical isolates, proximate farmlands	Air sampling	Morphological and molecular identification	<i>CLSI reference method, Vipecheck™</i>	10,2% of <i>A. fumigatus</i> isolates multiazole-resistant. 81% azole-resistant isolates contained the TR34/L98H mutation.	The presence of R34/L98H and TR46/Y121F/T289A isolates in hospital wards suggests that azole-resistant <i>A. fumigatus</i> transmission could have a nosocomial origin.	Chen et al. (2019)
Epidemiology and antifungal susceptibility profile of <i>Aspergillus</i> species: comparison between environmental and clinical isolates from patients with hematologic malignancies	South Korea	One hospital, indoor/ outdoor, and <i>Aspergillus</i> clinical isolates	Air sampling	Morphological and molecular identification	<i>CLSI reference method</i>	Resistance rates to any azole: <i>Aspergillus fumigatus</i> 7%, <i>A. niger</i> 4%, and <i>A. flavus</i> 5%. Different TR34/L98H mutations were found in <i>A. fumigatus</i> azole-resistant isolates.	The azole resistance rate was not different between clinical and environmental isolates.	Cho et al. (2019)

Table 2 Continued

Database	Title	Country	Environment description	Sampling methods	Fungal identification	Azole resistance	Results	Conclusions	References
	<i>Aspergillus</i> species collected from environmental air samples in Portugal-molecular identification, antifungal susceptibility and sequencing of <i>cyp51A</i> gene on <i>A. fumigatus sensu stricto</i> itraconazole-resistant	Portugal	Two hospitals, indoor/outdoor, and one waste water plant	Air sampling	Morphological and molecular identification	<i>EUCAST reference method</i>	<i>A. fumigatus sensu stricto</i> isolates: 48 isavuconazole-, 12 itraconazole- and 21 posaconazole-resistant. <i>Aspergillus</i> cryptic species: almost all were resistant to at least three azoles. None of the environmental isolates showed mutations on the <i>cyp51A</i> gene.	Most environmental isolates were <i>A. fumigatus sensu stricto</i> , and some were azole-resistant. The environment presence of cryptic species can be a risk factor for outpatients, increasing the probability of fungal infection while they are in ambulatory treatment.	Monteiro et al. (2019)
	Exposure assessment in one central hospital: A multi-approach protocol to achieve an accurate risk characterization	Portugal	One hospital, indoor	Air sampling, EDC sampling, settled dust, surface swabs	Morphological and molecular identification	<i>EUCAST reference method (adapted)</i>	<i>A. versicolor</i> and two other filamentous fungal species grew on voriconazole. <i>Penicillium</i> sp. grew on itraconazole and posaconazole, and <i>Chrysosporium</i> sp. on posaconazole.	Fungal contamination of indoor environments of hospitals and consequent exposure to less susceptible or resistant isolates may lead to complications in the management of fungal infections	Viegas et al. (2019a)

environment. If azole-resistant fungi are present in hospital environment, patients can potentially inhale resistant spores and consequently acquire an azole-resistant infection (Snelders *et al.*, 2009). This is particularly important in immunocompromised patients, more susceptible to developing invasive fungal infections (Snelders *et al.*, 2009; Mohammadi *et al.*, 2016; Cho *et al.*, 2019; Monteiro *et al.*, 2019; Savastano *et al.*, 2016). Therefore, the surveillance of azole-resistance in the hospital environment is of utmost importance so that healthcare facilities are prepared to control dissemination sources and provide a secure environment for their occupants (Caetano *et al.*, 2019).

In this review it was verified that the assessment of azole-resistance in the hospital environment is still incipient, as perceived by the limited number of studies ($n=12$) published in the last decade, in spite of this environment being commonly related to infection acquisition (Wilson, 2018). In addition, the evaluation of azole resistance in the hospital environment in genera other than *Aspergillus* is not common, which makes it difficult to understand the extent of the azole resistance problem in this environment. In order to assess the risk of acquiring azole-resistant fungal infections in healthcare facilities, evaluations of the hospital indoor environment are crucial (Caetano *et al.*, 2019) and further studies on surveillance of azole resistance both in clinical isolates and in the environment are recommended (Annon, 2017; Talbot *et al.*, 2018; Chen *et al.*, 2019).

The most common microbial sampling strategy used in indoor environments is air sampling, either by active methods such as impaction or impinger, or passive air sampling by surface swabbing, dust collection, settled plates or electrostatic dust collectors. In the 12 analyzed studies different sampling strategies were used. Active air sampling, the gold standard to evaluate indoor air as it is easily standardized and comparable, was the strategy used in the majority of the analyzed studies (10 out of 12), of which five used it exclusively (San Juan *et al.*, 2017; Loeffert *et al.*, 2018; Chen *et al.*, 2019; Cho *et al.*, 2019; Monteiro *et al.*, 2019). The parallel use of active and passive air sampling methods was described in five studies (Panagopoulou *et al.*, 2007; Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Mohammadi *et al.*, 2016; Viegas *et al.*, 2019a), and two studies resorted to passive sampling only (Savastano *et al.*, 2016; Caetano *et al.*, 2019). Since active air sampling methods allow the collection of contamination load only over a short period of time (e.g., minutes), and passive air sampling methods collect contamination load over a long period of time (from days to several months), the combination of both can provide a more precise and in-depth assessment of the environment and be used for a more accurate evaluation of exposure risks (Viegas *et al.*, 2019b). Moreover, passive air sampling is more economic and less intrusive, the drawback being the difficulty in comparing results obtained by different means (Méheust *et al.*, 2014). Considering the hospital environment, the different activities performed there and limited access to specific areas, such as intensive care units or transplantation areas, it is easily understandable that less intrusive sampling methods are advantageous, as they do not require the presence of an external individual during long-term sampling campaigns. Noteworthy, passive air sampling may also enable the assessment of a broader range of mycobiota (Viegas *et al.*, 2019a) or evaluate microbial contamination in critical sources involved in infection transmission such as hands (in *Candida* sp. transmission) (Savastano *et al.*, 2016) or HVAC filters (in reaerosolization of fungal spores) (Caetano *et al.*, 2019) and, thus, better predict exposure risks. Therefore, a sampling strategy for hospital environments should consider more than one sampling method (Caetano *et al.*, 2019; Viegas *et al.*, 2019a).

Culture-based methods are of utmost importance for the measurement of viable microbial contamination and prediction of clinical significance being crucial in exposure assessment studies in health care facilities (Järvi *et al.*, 2018). Interestingly, a significant number of studies resorted to molecular methods for fungal identification complementary to conventional culture-based methods ($n=8$). Considering the growing role of molecular methods in species recognition, the “*Aspergillus* Systematics in the Genomic Era” working group proposed specific recommendations that include the use of ITS regions for inter section level identification and the β -tubulin locus for identification of individual species in the various *Aspergillus* sections (Balajee *et al.*, 2007). Fungal identification should, thus, rely both on culture-based and on molecular methods as closely related species with similar morphology (also referred to as cryptic species) are only distinguishable at the molecular level, while presenting variable anti-fungal susceptibility profiles (Lamoth, 2016; Cho *et al.*, 2019). For example, while resistance to triazoles is rare among *A. fumigatus sensu stricto*, decreased susceptibility to azoles and other antifungal agents is often observed for cryptic species (Alastruey-Izquierdo *et al.*, 2014). Moreover, in environmental samples with composite microbial burden, the competition for nutrients and the advantage of some species over others regarding media composition and incubation conditions (e.g., moisture, temperature) may hinder the visible growth of important fungi with toxigenic or pathogenic potential, thus, representing an increased risk in health care facilities (Caetano *et al.*, 2019).

Since it was postulated that azole resistance has an environmental origin, as azole-resistant aspergillosis was reported in azole-naïve patients (Verweij *et al.*, 2002; Dannaoui *et al.*, 1999; Snelders *et al.*, 2009), the search for azole-resistance in the environment increased. In this review, six studies investigated the presence of azole resistance indoor and outdoor the hospital environment (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Loeffert *et al.*, 2018; Chen *et al.*, 2019; Cho *et al.*, 2019; Monteiro *et al.*, 2019). Noteworthy, five of them concluded that the presence of isolates from the *Fumigati* section of *Aspergillus* sp. that were triazole-resistant or susceptible to azoles at high MIC's in the hospital environment or its surroundings was a risk for susceptible patients (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Loeffert *et al.*, 2018; Chen *et al.*, 2019; Monteiro *et al.*, 2019). It appears that the development of resistant fungal isolates can be related to the widespread of fungicides in agricultural practices for plant protection and in material preservation such as paint, paper and wood, while it is also common in mattresses. Isolates that develop resistance to fungicides might be cross-resistant to medical triazoles (Verweij *et al.*, 2016). Azole resistance can also be either specific to the microorganism (e.g., innate resistance of Mucorales order to voriconazole Caramalho *et al.*, 2017) or acquired by previously susceptible microorganisms in the course of therapy. Antifungal resistance can be microbiologic, clinical or both. Microbiologic resistance occurs when the fungal growth is inhibited by a much higher concentration of an antifungal compound in comparison to the range seen with wild-type strains, whereas clinical antifungal resistance is defined as when the concentration of an antifungal

agent is associated with a higher risk of therapeutic failure. When it is both clinical and microbiologic, the resistance is present when the isolates are not inhibited by the usual concentrations of an antifungal compound, with regular dosage schedules and/or when they demonstrate MIC's (minimum inhibitory concentrations) that fall within the range where it is likely to be present a specific microbial resistance, and the clinical efficacy against the isolate is not reliably shown in studies (Pfalter, 2012).

Present treatment options of fungal infections include polyenes, echinocandins, and triazoles. Azole resistance in clinical isolates of *A. section Fumigati* with *in vitro* resistance to itraconazole and voriconazole is increasing over the recent years and is a concern in the management of invasive aspergillosis (Snelders *et al.*, 2011). Azoles inhibit the ergosterol biosynthesis pathway through the inhibition demethylation of sterol 14- α -demethylase (CYP51). Azole resistance is commonly due to mutations in *cyp51A* gene target for azole antifungals (Snelders *et al.*, 2008). This resistance mechanism was recovered both in clinical and environmental samples (soil, compost, seeds, air, water, surface swabs) in four analyzed studies (Snelders *et al.*, 2009; Ahmad *et al.*, 2014; Chen *et al.*, 2019; Cho *et al.*, 2019), with one study identifying multi-azole-resistant environmental isolates from two hospitals and one waste water plant with no mutation on the *cyp51A* gene (Monteiro *et al.*, 2019). The mutations related to azole resistance found in these studies, located at the TR34/L98H and the TR46 codons in the CYP51A gene, have also been reported as some of the most commonly found mutations in the environment (Güngör *et al.*, 2018; Wiederhold *et al.*, 2016). This might indicate that the mutations found in the fungal species in hospital environments may come from the outdoor environment.

Standard antifungal susceptibility tests have been described for the detection of azole resistance in a reduced number of fungal species, including *Aspergillus* and *Candida* spp., with the Clinical and Laboratory Standards Institute (CLSI) (used in 7 studies) and the European Committee on Antimicrobial Susceptibility Testing (antifungal susceptibility testing [AFST]-EUCAST) (used in 5 studies). These guidelines for *in vitro* triazole testing in standardized conditions are mainly applied for the analysis of clinical isolates (EUCAST, 2019). Since *in vitro* triazole screening is not routinely performed in environmental isolates comprehensive studies on the antifungal susceptibility patterns are lacking. Moreover, these guidelines do not allow extensive analysis of complex and multi-contaminated samples, such as environmental samples.

The majority of the studies assessed the azole resistance among *Aspergillus* species, mainly from the *Fumigati* section. Further assessments of azole-resistance in clinical environments in other genera will provide important information to understand the extension of azole resistance in this type of environment. Comparing the articles, from 2007 to 2019, there has been an increase in the fungal species identified inside healthcare facilities' indoor environments that also displayed azole resistance or susceptibility to azoles only at high MIC's. The sophistication of microbiological and molecular methods of identification allied to a wide diversity of sampling methods will unveil a better characterization of the environmental bioburden as well as the contamination risk assessment in healthcare institutions. A better understanding of both factors is crucial for healthcare institutions to implement more effective practices and adequate cleaning and hygienization procedures to ensure the quality of their environment as well as the reduction of the risk of drug resistant infections.

Overall, the presence of azole-resistant fungi in the clinical environment and its relation with hospital-acquired azole-resistant infections in susceptible patients has been demonstrated and alert for the need of more research and environmental sampling, in addition to international surveillance studies of clinical isolates, in order to determine and track the spread of azole resistance in the environment.

Introduction

It has been generally recognized by researchers and regulators that the expected climate change constitutes an important driver that will affect food sector, representing a public health issue that deserves particular attention. In one hand, climate change threatens our ability to ensure global food security, eradicate poverty and achieve sustainable development (Berbegal *et al.*, 2019). Climate change is associated with increasing temperatures and more extreme rainfall; it alters relationships among crops, pests, pathogens, and weeds; and it exacerbates several trends including declines in pollinating insects, increasing water scarcity, increasing ground-level ozone concentrations, and fishery declines (Myers *et al.*, 2017). Agricultural productivity is affected by changing rainfall patterns, drought, flooding and the geographical redistribution of pests and diseases (Anderson *et al.*, 2020), with consequent implications in the food availability, a key requirement for food security (Fig. 1).

On the other hand, despite less debated, climate change could also affect food safety (Miraglia *et al.*, 2009) (Fig. 1), namely through the occurrence of food safety hazards at various stages of food chain, from “farm to fork”. The tendency to increase the use of agrochemicals to balance the effects of more frequent extreme weather events and water scarcity in some regions could become more frequent. In addition to pesticide residues, both chemical and microbiological risks are expected to impair food and feed safety as a consequence of climate change: in particular mycotoxins, marine biotoxins (phycotoxins), trace metals, among others (Miraglia *et al.*, 2009; Tirado *et al.*, 2010; Assunção *et al.*, 2018b; FAO, 2020).

Among the issues in food safety, the rise of crop diseases due to toxigenic fungi and the contamination of crops by toxic secondary metabolites – mycotoxins – constitute aspects of major importance (Moretti *et al.*, 2019). Mycotoxins are produced by different types of fungus belonging primarily to genera *Aspergillus*, *Penicillium*, and *Fusarium*. Although these low molecular weight toxic compounds occur worldwide and represent a global public and animal health threat, their prevalence and concentrations in food and feed may vary due to geographic and climatic differences, posing a serious risk to human and animal health worldwide (Ksenija, 2018; Moretti *et al.*, 2019). The mycotoxins of greatest concern to food and feed safety include aflatoxins, fumonisins, ochratoxins, trichothecenes, and zearalenone.

Fig. 1 Impact of climate change on food and agriculture systems.

Table 1 Maximum permitted levels of mycotoxins in food and feed in the EU

	Foodstuffs	Maximum levels ($\mu\text{g/kg}$) ^a	Animal feed	Maximum levels (mg/kg) ^{b,c}
Aflatoxin B ₁	Cereals, cereal-based products, nuts/dried fruits, spices	2.0–12.0	Feed materials, complementary and complete feed	0.005–0.02
Sum of Aflatoxins B ₁ , B ₂ , G ₁ , and G ₂		4.0–15.0		
Aflatoxin M ₁	Milk and milk products	0.050		
Aflatoxin B ₁	Foods intended for infants and young	0.10		
Aflatoxin M ₁	children (e.g., cereal-based foods)	0.025		

^aRegulation (EC) 1881/2006;^bDirective 2002/32/EC;^cMaximum content in mg/kg (ppm) relative to a feed with a moisture content of 12%.

Aflatoxins, the most toxic of mycotoxins, are genotoxic, carcinogenic and immunosuppressive substances, and cause both acute and chronic toxicity (Wu *et al.*, 2014). The four major aflatoxins known are B₁, B₂, G₁, and G₂. Aflatoxin B₁ (AFB₁) is the most potent naturally occurring chemical liver carcinogen known, being considered a significant risk factor for hepatocellular carcinoma (HCC) and classified as Group 1 (carcinogenic to humans) by the International Agency for Research on Cancer (IARC, 2012). Additionally, when animals that are intended for dairy production consume aflatoxin-contaminated feed, a metabolite, aflatoxin M₁, is excreted in the milk (Strosnider *et al.*, 2006).

Cereals are often the most severely affected crops, and because they are a staple food for a large portion of humanity, mycotoxins are considered the most prevalent food-related health risk in field crops (Moretti *et al.*, 2019). Regarding aflatoxins, they are reported in several agricultural crops, mainly maize, peanuts, pistachio nuts, and cottonseeds (CAST, 2003). At the European level, regulations were established to set maximum levels of aflatoxins in food and feed (Table 1), contributing to reduce the human and animal exposure, and consequently the associated risk (European Commission, 2002, 2006).

The possible change in patterns of aflatoxin occurrence in food and feed crops due to climate change is a matter of concern that may require anticipatory actions (Battilani *et al.*, 2016; Van der Fels-Klerx *et al.*, 2016). During the last years, some studies were performed concerning the potential impact of climate change in the aflatoxins food and feed contamination (Van der Fels-Klerx *et al.*, 2016). Based on the results obtained, the authors were unanimous in considering different areas of Europe as Eastern Europe, Balkan Peninsula, and the Mediterranean regions as the most concerned areas, including the Iberian Peninsula. The authors also referred that aflatoxin contamination above the legal limit are expected to become more frequent in the future (Battilani *et al.*, 2016; Van der Fels-Klerx *et al.*, 2016).

Consequently, the establishment of the environmental conditions that determine the fungi growth, survival, and/or interactions with plants is essential to better understand the variation in the population structures of mycotoxigenic fungi and their ability to produce mycotoxins (Medina *et al.*, 2017), and to anticipate the potential impact of climate change.

Building on what was referred, through an overview of the current situation of aflatoxins contamination in food and feed in Portugal and Spain (Iberian Peninsula), the present article aims to answer two main questions: Are aflatoxins a current concern in the Iberian Peninsula? How the climate change could impact aflatoxins contamination and the risk of human exposure in Iberian Peninsula?

Are Aflatoxins a Current Concern in the Iberian Peninsula?

The occurrence of aflatoxins in cereal-based products intended for animal and human consumption has been reported in Portugal and Spain. Occurrence of aflatoxins in cereals and cereal-based products (food and feed) reported in 2007–2019 are summarized in Tables 2 and 3 for Portugal and Spain, respectively.

The pattern of occurrence of aflatoxins in Portugal is what is generally verified in high-income countries, i.e., higher frequencies with usually low levels or levels below the regulation of contamination. Despite in Portugal a monitoring system is evaluating food and feed according to the EU regulations, these data are not publically available. Consequently, no published data are available for cereal grains and scarce data are available regarding the occurrence of aflatoxins in feed.

The occurrence of aflatoxins in Spain follows a similar pattern to the one presented for Portugal, i.e., higher frequencies with usually low levels or levels below the regulation of contamination. In Spain there are several studies reporting the occurrence of aflatoxins in cereals (maize, barley, wheat, malt, rice) and in cereal-based products (breakfast cereals, baby food, pasta, flours, and bread), and a few studies in feed.

Climate change and the health impact of aflatoxins exposure in Portugal – An overview. Food Additives and Contaminants – Part A Chemistry, Analysis, Control, Exposure and Risk Assessment 35 (8), 1610–1621. Available at: <https://doi.org/10.1080/19440049.2018.1447691>.

To summarize, aflatoxins are occurring in food and feed products available in Portugal and Spain, generally in levels that not exceed established maximum limits.

Climate Change and the Impact on Aflatoxins Contamination and the Risk of Human Exposure

Fungal growth and mycotoxins' biosynthesis are influenced by several environmental factors such as the temperature, relative humidity, rainfall and water activity. Despite fungi can grow in a wide range of water activity and temperature, the optimal conditions for mycotoxins' biosynthesis are more restrict (Battilani *et al.*, 2020; Tai *et al.*, 2020). Data on ecological needs are available for *A. flavus*, with a suitable range of temperatures between 25–35°C and 28–30°C for fungal growth and aflatoxins production, respectively, and a suitable water activity ranging from 0.95 to 1.0 (Battilani *et al.*, 2020). As such, mycotoxins are highly dependent on climate, plant and storage-associated problems, but also influenced by non-infectivity factors (e.g., bioavailability of nutrients, insect damage, and other pest attack), that are also driven by climatic conditions (Medina *et al.*, 2014; Assunção *et al.*, 2018b).

Regarding how the climate has evolved in the last years, in Spain, climatic data have been registered officially since the 19th century (year 1869) (Brunet *et al.*, 2006). According to the Spanish State Meteorology Agency (AEMET) and after analyzing the annual mean temperature in mainland and Balearic Islands between 1900 and 2010, a general increasing trend in mean temperatures could be observed specially between the 70's until 2000. For this period and in terms of yearly accumulated rainfalls, a high variability was observed at different time scales (Agencia Estatal de Meteorología, 2020). Similar results were obtained in a paper presenting daily adjusted dataset composed of 22 Spanish daily temperatures records (the longest available at the time of the analysis) over 1850 and 2003 (Brunet *et al.*, 2006). This analysis showed that over mainland Spain highly significant rates of temperature increases occurred for maximum and minimum temperatures (0.12°C/decade and 0.10°C/decade, respectively) over 1850–2003. Likewise, the climatic trends in Portugal follow a similar pattern. From 1970 to nowadays, annual mean temperatures are increasing and there is a trend showing the increase of temperatures and a reduction of rainfall periods (Nunes *et al.*, 2020; Portal do Clima, 2020).

Considering the influence of environmental factors on fungal growth and mycotoxins' production, an impact of climate change in the occurrence of mycotoxins in cereals crops is also expected. There are several predictions relating climate change and crop production. For Southern Europe, it is foreseen an increase of 4–5°C with longer drought periods, that may result in increasing desertification and decreasing crop yields (Medina *et al.*, 2017). The impact of climate change in crops contamination by aflatoxins was predicted through a modeling approach that considered three scenarios: the present, +2°C and +5°C. The enlargement of

Note: Adapted from Echarri, E., Vettorazzi, A., Lizarraga, E., *et al.*, 2019. Review of the analytical methodologies and occurrence data of aflatoxins in cereals and cereal-based foods in Spain. In: Kintzios, S., Mavrikou, S. (Eds.), Aflatoxins: Biochemistry, Toxicology, Public Health, Policies and Modern Methods of Analysis. New York: Nova Science Publishers, pp. 207–243.

aflatoxin risk zones could increase human and animal population chronic exposures to these mycotoxins. AFB₁ was predicted to become a food safety issue in maize in Europe, especially in the + 2°C scenario, the scenario of climate change considered as most probable in the coming years (Battilani *et al.*, 2016).

Under this context, considering the recently published EFSA's risk assessment of aflatoxins (EFSA Panel on Contaminants in the Food Chain CONTAM, 2020), the intake of total aflatoxins ranged in Portugal between 0.36 ng kg⁻¹ bw day⁻¹ (in infants) and

^aMoE determined for exposure to AFB₁ considering a BMDL₁₀ of 0.4 $\mu\text{g kg}^{-1} \text{ bw day}^{-1}$ for the induction of HCC by AFB₁ in male rats.

IAN-AF = National Food, Nutrition, and Physical Activity Survey of the Portuguese General Population; ENALIA = Spanish National Food Survey on children and adolescents; ENALIA2 = Spanish National Food Survey on adults, the elderly and pregnant women; AFs = Aflatoxins (Sum of AFB₁, AFB₂, AFG₁, AFG₂, AFM₁); AFB₁ = Aflatoxin B₁; LB = Lower-bound approach; UB = Upper-bound approach; MoE = Margin of Exposure.

Note: Adapted from EFSA Panel on Contaminants in the Food Chain (CONTAM), 2020. Risk assessment of aflatoxins in food. EFSA Journal 18 (3). Available at: <https://doi.org/10.2903/j.efsa.2020.6040>.

5.67 $\text{ng kg}^{-1} \text{ bw day}^{-1}$ (in other children, aged between 36 months and 10 years) $\text{ng kg}^{-1} \text{ bw day}^{-1}$, and in Spain between 0.42 $\text{ng kg}^{-1} \text{ bw day}^{-1}$ (in infants) and 5.68 $\text{ng kg}^{-1} \text{ bw/day}$ (in other children, aged between 36 months and 10 years) (Table 4). In a very tentative exercise considering the exposure of Portuguese and Spanish population reported in the EFSA's risk assessment, a prediction of the associated risk was estimated through the calculation of the Margin of Exposure (MoE), as presented in Table 4. These results also reinforced that children aged between 36 months and 10 years (identified in the table as other children) is the age group under higher risk in the both countries, presenting the lowest MoE. Consequently, careful attention should be dedicated to aflatoxins exposure in the Iberian Peninsula, taking into consideration the already identified risk and the potential of increasing in a climate change scenario.

Considering the carcinogenic effects associated with human exposure to aflatoxins, namely hepatocellular carcinoma, and the fact that exposure to aflatoxins in Iberian Peninsula is nowadays a reality (Tables 2 and 3), the impact on health was previously estimated and reported, quantifying the Disability-Adjusted Life Years (DALY). In 2015, the WHO estimated the burden associated with exposure to aflatoxins for the Europe region, where Portugal and Spain are included as 0.3 (0.1–0.7) DALY/year/100k (WHO, 2015). Assunção *et al.* (2018a), estimated a similar number of DALY/100,000 for Portugal, 0.08–0.30, based on previous exposure reports (Assunção *et al.*, 2018b). Recently, and based on data obtained under a human biomonitoring study, Martins *et al.* (2020) estimated that exposure to aflatoxins in Portugal corresponds to 0.13 annual extra-cases of HCC and 1.7 DALY/100,000 (Martins *et al.*, 2020).

European countries are already capacitated to anticipate and mitigate the effects of occurrence of mycotoxins in cereal crops. The effort of European countries has mainly an economic burden, i.e., the costs involved with sampling and analysis to meet regulatory and contract requirements, and hidden costs of destroyed or returned shipments and the time and expense of sourcing and purchasing replacement items (Logrieco *et al.*, 2018; Ndemera *et al.*, 2020). The scenarios that point to an increase of food safety issues will imply a continuous effort and a tighter surveillance of occurrence of mycotoxins. It is also possible that the impact of climate change will not be homogeneous within each country. As an example, Navarra, a region in the north of Spain, could be divided into four climatic areas and seven zones. Ibáñez-Vea *et al.* (2012) evaluated the occurrence of aflatoxins in 123 barley samples and compared samples from the central and southern region of Navarra (a region of Spain). In this study, the differences were minimal, except for AFG₁ that showed higher levels in one zone of the southern region. However, the samples were collected in two different years (2007 and 2008) and these results could also be biased by the different climatic conditions of each year. Indeed, some statistical difference were observed between years. Unfortunately, the study was not designed to collect the climatic records which refrain to have a clearer scenario.

Altogether, these results highlight the need for a continuous surveillance of levels of aflatoxins on feed and food consumed in Europe. The development of human biomonitoring studies is also needed so that the health effects associated with exposure to aflatoxins can be anticipated.

Conclusions and Future Perspectives

The occurrence of aflatoxins in foods marketed in Iberian Peninsula is proved to be a reality and a concern from a public health point of view. Additionally, and considering the quality control strategies implemented from farm to fork in Europe, the economic burden related with the occurrence of these mycotoxins should not be discarded. The environmental factors are a major influence on the levels of occurrence and this European region is foreseen to become affected in a near future, if climatic factors follow the current trends. New and more effective strategies to prevent the occurrence of aflatoxins in foods and consequently the associated health effects are needed in a near future. The development of monitoring strategies, not only for occurrence in foods and feed but also for monitoring the exposure of population, is an area requiring further efforts.
